The statements of a `finally` block are always executed when control leaves a `try` statement. This is true whether the control transfer occurs as a result of normal execution, as a result of executing a `break`, `continue`, `goto`, or `return` statement, or as a result of propagating an exception out of the `try` statement. If control reaches the end point of the `finally` block without an exception being propagated, control is transferred to the end point of the `try` statement.

If an exception is thrown during execution of a `finally` block, and is not caught within the same `finally` block, the exception is propagated to the next enclosing `try` statement. If another exception was in the process of being propagated, that exception is lost. The process of propagating an exception is discussed further in the description of the `throw` statement (§12.10.6).

Example: In the following code

C#

```
public class Test
{
    static void Main()
    {
        try
        {
            Method();
        }
        catch (Exception ex) when (ExceptionFilter(ex))
        {
            Console.WriteLine("Catch");
        }

        bool ExceptionFilter(Exception ex)
        {
            Console.WriteLine("Filter");
            return true;
        }
    }

    static void Method()
    {
        try
        {
            throw new ArgumentException();
        }
        finally
        {
            Console.WriteLine("Finally");
        }
    }
}
```

the method `Method` throws an exception. The first action is to examine the enclosing `catch` clauses, executing any *exception filters*. Then, the `finally` clause in `Method` executes before control transfers to the enclosing matching `catch` clause. The resulting output is:

Console

```
Filter
Finally
Catch
```

end example

The `try` block of a `try` statement is reachable if the `try` statement is reachable.

A `catch` block of a `try` statement is reachable if the `try` statement is reachable.

The `finally` block of a `try` statement is reachable if the `try` statement is reachable.

The end point of a `try` statement is reachable if both of the following are true:

- The end point of the `try` block is reachable or the end point of at least one `catch` block is reachable.
- If a `finally` block is present, the end point of the `finally` block is reachable.

12.12 The checked and unchecked statements

The `checked` and `unchecked` statements are used to control the *overflow-checking context* for integral-type arithmetic operations and conversions.

ANTLR

```
checked_statement
    : 'checked' block
    ;

unchecked_statement
    : 'unchecked' block
    ;
```

The `checked` statement causes all expressions in the *block* to be evaluated in a checked context, and the `unchecked` statement causes all expressions in the *block* to be evaluated in an unchecked context.

The `checked` and `unchecked` statements are precisely equivalent to the `checked` and `unchecked` operators ([§11.7.18](#)), except that they operate on blocks instead of expressions.

12.13 The lock statement

The `lock` statement obtains the mutual-exclusion lock for a given object, executes a statement, and then releases the lock.

ANTLR

```
lock_statement
    : 'lock' '(' expression ')' embedded_statement
    ;
```

The *expression* of a `lock` statement shall denote a value of a type known to be a *reference*. No implicit boxing conversion (§10.2.9) is ever performed for the *expression* of a `lock` statement, and thus it is a compile-time error for the expression to denote a value of a *value_type*.

A `lock` statement of the form

```
lock (x) ...
```

where `x` is an expression of a *reference_type*, is precisely equivalent to:

```
C#

bool __lockWasTaken = false;
try
{
    System.Threading.Monitor.Enter(x, ref __lockWasTaken);
    ...
}
finally
{
    if (__lockWasTaken)
    {
        System.Threading.Monitor.Exit(x);
    }
}
```

except that `x` is only evaluated once.

While a mutual-exclusion lock is held, code executing in the same execution thread can also obtain and release the lock. However, code executing in other threads is blocked from obtaining the lock until the lock is released.

12.14 The using statement

The `using` statement obtains one or more resources, executes a statement, and then disposes of the resource.

```
ANTLR

using_statement
: 'using' '(' resource_acquisition ')' embedded_statement
;

resource_acquisition
: local_variable_declaration
```

```
| expression  
;
```

A **resource** is a class or struct that implements the `System.IDisposable` interface, which includes a single parameterless method named `Dispose`. Code that is using a resource can call `Dispose` to indicate that the resource is no longer needed.

If the form of *resource_acquisition* is *local_variable_declaration* then the type of the *local_variable_declaration* shall be either dynamic or a type that can be implicitly converted to `System.IDisposable`. If the form of *resource_acquisition* is *expression* then this expression shall be implicitly convertible to `System.IDisposable`.

Local variables declared in a *resource_acquisition* are read-only, and shall include an initializer. A compile-time error occurs if the embedded statement attempts to modify these local variables (via assignment or the `++` and `--` operators), take the address of them, or pass them as `ref` or `out` parameters.

A `using` statement is translated into three parts: acquisition, usage, and disposal. Usage of the resource is implicitly enclosed in a `try` statement that includes a `finally` clause. This `finally` clause disposes of the resource. If a `null` resource is acquired, then no call to `Dispose` is made, and no exception is thrown. If the resource is of type `dynamic` it is dynamically converted through an implicit dynamic conversion (§10.2.10) to `IDisposable` during acquisition in order to ensure that the conversion is successful before the usage and disposal.

A `using` statement of the form

```
C#
```

```
using (ResourceType resource= «expression» ) «statement»
```

corresponds to one of three possible expansions. When `ResourceType` is a non-nullable value type or a type parameter with the value type constraint (§14.2.5), the expansion is semantically equivalent to

```
C#
```

```
{  
    ResourceType resource = «expression»;  
    try  
    {  
        «statement»;  
    }  
    finally
```

```
{
    ((IDisposable)resource).Dispose();
}
```

except that the cast of `resource` to `System.IDisposable` shall not cause boxing to occur.

Otherwise, when `ResourceType` is `dynamic`, the expansion is

```
C#
{
    ResourceType resource = «expression»;
    IDisposable d = resource;
    try
    {
        «statement»;
    }
    finally
    {
        if (d != null)
        {
            d.Dispose();
        }
    }
}
```

Otherwise, the expansion is

```
C#
{
    ResourceType resource = «expression»;
    try
    {
        «statement»;
    }
    finally
    {
        IDisposable d = (IDisposable)resource;
        if (d != null)
        {
            d.Dispose();
        }
    }
}
```

In any expansion, the `resource` variable is read-only in the embedded statement, and the `d` variable is inaccessible in, and invisible to, the embedded statement.

An implementation is permitted to implement a given *using_statement* differently, e.g., for performance reasons, as long as the behavior is consistent with the above expansion.

A `using` statement of the form:

```
C#  
  
using («expression») «statement»
```

has the same three possible expansions. In this case `ResourceType` is implicitly the compile-time type of the *expression*, if it has one. Otherwise the interface `IDisposable` itself is used as the `ResourceType`. The `resource` variable is inaccessible in, and invisible to, the embedded *statement*.

When a *resource_acquisition* takes the form of a *local_variable_declaration*, it is possible to acquire multiple resources of a given type. A `using` statement of the form

```
C#  
  
using (ResourceType r1 = e1, r2 = e2, ..., rN = eN) «statement»
```

is precisely equivalent to a sequence of nested `using` statements:

```
C#  
  
using (ResourceType r1 = e1)  
using (ResourceType r2 = e2)  
...  
using (ResourceType rN = eN)  
«statement»
```

Example: The example below creates a file named `log.txt` and writes two lines of text to the file. The example then opens that same file for reading and copies the contained lines of text to the console.

```
C#  
  
class Test  
{  
    static void Main()  
    {  
        using (TextWriter w = File.CreateText("log.txt"))  
        {  
            w.WriteLine("This is line one");  
            w.WriteLine("This is line two");  
        }  
    }  
}
```

```

using (TextReader r = File.OpenText("log.txt"))
{
    string s;
    while ((s = r.ReadLine()) != null)
    {
        Console.WriteLine(s);
    }
}
}

```

Since the `TextWriter` and `TextReader` classes implement the `IDisposable` interface, the example can use `using` statements to ensure that the underlying file is properly closed following the write or read operations.

end example

12.15 The yield statement

The `yield` statement is used in an iterator block (§12.3) to yield a value to the enumerator object (§14.14.5) or enumerable object (§14.14.6) of an iterator or to signal the end of the iteration.

ANTLR

```

yield_statement
: 'yield' 'return' expression ';'
| 'yield' 'break' ';'
;

```

`yield` is a contextual keyword (§6.4.4) and has special meaning only when used immediately before a `return` or `break` keyword.

There are several restrictions on where a `yield` statement can appear, as described in the following.

- It is a compile-time error for a `yield` statement (of either form) to appear outside a *method_body*, *operator_body*, or *accessor_body*.
- It is a compile-time error for a `yield` statement (of either form) to appear inside an anonymous function.
- It is a compile-time error for a `yield` statement (of either form) to appear in the `finally` clause of a `try` statement.
- It is a compile-time error for a `yield return` statement to appear anywhere in a `try` statement that contains any *catch_clauses*.

Example: The following example shows some valid and invalid uses of `yield` statements.

C#

```
delegate IEnumerable<int> D();

IEnumerator<int> GetEnumerator()
{
    try
    {
        yield return 1; // Ok
        yield break;   // Ok
    }
    finally
    {
        yield return 2; // Error, yield in finally
        yield break;   // Error, yield in finally
    }
    try
    {
        yield return 3; // Error, yield return in try/catch
        yield break;   // Ok
    }
    catch
    {
        yield return 4; // Error, yield return in try/catch
        yield break;   // Ok
    }
    D d = delegate
    {
        yield return 5; // Error, yield in an anonymous function
    };
}

int MyMethod()
{
    yield return 1;    //Error, wrong return type for an iterator
    block
}
```

end example

An implicit conversion (§10.2) shall exist from the type of the expression in the `yield return` statement to the yield type (§14.14.4) of the iterator.

A `yield return` statement is executed as follows:

- The expression given in the statement is evaluated, implicitly converted to the yield type, and assigned to the `Current` property of the enumerator object.

- Execution of the iterator block is suspended. If the `yield return` statement is within one or more `try` blocks, the associated `finally` blocks are *not* executed at this time.
- The `MoveNext` method of the enumerator object returns `true` to its caller, indicating that the enumerator object successfully advanced to the next item.

The next call to the enumerator object's `MoveNext` method resumes execution of the iterator block from where it was last suspended.

A `yield break` statement is executed as follows:

- If the `yield break` statement is enclosed by one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all enclosing `try` statements have been executed.
- Control is returned to the caller of the iterator block. This is either the `MoveNext` method or `Dispose` method of the enumerator object.

Because a `yield break` statement unconditionally transfers control elsewhere, the end point of a `yield break` statement is never reachable.

13 Namespaces

Article • 2023-01-13 • 23 minutes to read

13.1 General

C# programs are organized using namespaces. Namespaces are used both as an “internal” organization system for a program, and as an “external” organization system—a way of presenting program elements that are exposed to other programs.

Using directives ([§13.5](#)) are provided to facilitate the use of namespaces.

13.2 Compilation units

A *compilation_unit* consists of zero or more *extern_alias_directives* followed by zero or more *using_directives* followed by zero or one *global_attributes* followed by zero or more *namespace_member_declarations*. The *compilation_unit* defines the overall structure of the input.

ANTLR

```
compilation_unit
: extern_alias_directive* using_directive* global_attributes?
  namespace_member_declaration*
;
```

A C# program consists of one or more compilation units. When a C# program is compiled, all of the compilation units are processed together. Thus, compilation units can depend on each other, possibly in a circular fashion.

The *extern_alias_directives* of a compilation unit affect the *using_directives*, *global_attributes* and *namespace_member_declarations* of that compilation unit, but have no effect on other compilation units.

The *using_directives* of a compilation unit affect the *global_attributes* and *namespace_member_declarations* of that compilation unit, but have no effect on other compilation units.

The *global_attributes* ([§21.3](#)) of a compilation unit permit the specification of attributes for the target assembly and module. Assemblies and modules act as physical containers for types. An assembly may consist of several physically separate modules.

The *namespace_member_declarations* of each compilation unit of a program contribute members to a single declaration space called the global namespace.

Example:

```
C#  
  
// File A.cs:  
class A {}  
// File B.cs:  
class B {}
```

The two compilation units contribute to the single global namespace, in this case declaring two classes with the fully qualified names `A` and `B`. Because the two compilation units contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

end example

13.3 Namespace declarations

A *namespace_declaration* consists of the keyword `namespace`, followed by a namespace name and body, optionally followed by a semicolon.

```
ANTLR  
  
namespace_declaration  
: 'namespace' qualified_identifier namespace_body ';' ?  
;  
  
qualified_identifier  
: identifier ('.' identifier)*  
;  
  
namespace_body  
: '{' extern_alias_directive* using_directive*  
  namespace_member_declaration* '}'  
;
```

A *namespace_declaration* may occur as a top-level declaration in a *compilation_unit* or as a member declaration within another *namespace_declaration*. When a *namespace_declaration* occurs as a top-level declaration in a *compilation_unit*, the namespace becomes a member of the global namespace. When a *namespace_declaration* occurs within another *namespace_declaration*, the inner

namespace becomes a member of the outer namespace. In either case, the name of a namespace shall be unique within the containing namespace.

Namespaces are implicitly `public` and the declaration of a namespace cannot include any access modifiers.

Within a *namespace_body*, the optional *using_directives* import the names of other namespaces, types and members, allowing them to be referenced directly instead of through qualified names. The optional *namespace_member_declarations* contribute members to the declaration space of the namespace. Note that all *using_directives* must appear before any member declarations.

The *qualified_identifier* of a *namespace_declaration* may be a single identifier or a sequence of identifiers separated by "." tokens. The latter form permits a program to define a nested namespace without lexically nesting several namespace declarations.

Example:

```
C#  
  
namespace N1.N2  
{  
    class A {}  
    class B {}  
}
```

is semantically equivalent to

```
C#  
  
namespace N1  
{  
    namespace N2  
    {  
        class A {}  
        class B {}  
    }  
}
```

end example

Namespaces are open-ended, and two namespace declarations with the same fully qualified name (§7.8.2) contribute to the same declaration space (§7.3).

Example: In the following code

C#

```
namespace N1.N2
{
    class A {}
}

namespace N1.N2
{
    class B {}
}
```

the two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `N1.N2.A` and `N1.N2.B`. Because the two declarations contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

end example

13.4 Extern alias directives

An *extern_alias_directive* introduces an identifier that serves as an alias for a namespace. The specification of the aliased namespace is external to the source code of the program and applies also to nested namespaces of the aliased namespace.

ANTLR

```
extern_alias_directive
    : 'extern' 'alias' identifier ';'
    ;
```

The scope of an *extern_alias_directive* extends over the *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing *compilation_unit* or *namespace_body*.

Within a compilation unit or namespace body that contains an *extern_alias_directive*, the identifier introduced by the *extern_alias_directive* can be used to reference the aliased namespace. It is a compile-time error for the *identifier* to be the word `global`.

The alias introduced by an *extern_alias_directive* is very similar to the alias introduced by a *using_alias_directive*. See [§13.5.2](#) for more detailed discussion of *extern_alias_directives* and *using_alias_directives*.

`alias` is a contextual keyword (§6.4.4) and only has special meaning when it immediately follows the `extern` keyword in an *extern_alias_directive*.

An error occurs if a program declares an extern alias for which no external definition is provided.

Example: The following program declares and uses two extern aliases, `X` and `Y`, each of which represent the root of a distinct namespace hierarchy:

```
C#
extern alias X;
extern alias Y;

class Test
{
    X::N.A a;
    X::N.B b1;
    Y::N.B b2;
    Y::N.C c;
}
```

The program declares the existence of the extern aliases `X` and `Y`, but the actual definitions of the aliases are external to the program. The identically named `N.B` classes can now be referenced as `X.N.B` and `Y.N.B`, or, using the namespace alias qualifier, `X::N.B` and `Y::N.B`. *end example*

13.5 Using directives

13.5.1 General

Using directives facilitate the use of namespaces and types defined in other namespaces. Using directives impact the name resolution process of *namespace_or_type_names* (§7.8) and *simple_names* (§11.7.4), but unlike declarations, *using directives* do not contribute new members to the underlying declaration spaces of the compilation units or namespaces within which they are used.

```
ANTLR
```

```
using_directive
: using_alias_directive
| using_namespace_directive
| using_static_directive
;
```

A *using_alias_directive* (§13.5.2) introduces an alias for a namespace or type.

A *using_namespace_directive* (§13.5.3) imports the type members of a namespace.

A *using_static_directive* (§13.5.4) imports the nested types and static members of a type.

The scope of a *using_directive* extends over the *namespace_member_declarations* of its immediately containing compilation unit or namespace body. The scope of a *using_directive* specifically does not include its peer *using_directives*. Thus, peer *using_directives* do not affect each other, and the order in which they are written is insignificant. In contrast, the scope of an *extern_alias_directive* includes the *using_directives* defined in the same compilation unit or namespace body.

13.5.2 Using alias directives

A *using_alias_directive* introduces an identifier that serves as an alias for a namespace or type within the immediately enclosing compilation unit or namespace body.

ANTLR

```
using_alias_directive
    : 'using' identifier '=' namespace_or_type_name ';'
    ;
```

Within global attributes and member declarations in a compilation unit or namespace body that contains a *using_alias_directive*, the identifier introduced by the *using_alias_directive* can be used to reference the given namespace or type.

Example:

C#

```
namespace N1.N2
{
    class A {}
}
namespace N3
{
    using A = N1.N2.A;

    class B: A {}
}
```

Above, within member declarations in the `N3` namespace, `A` is an alias for `N1.N2.A`, and thus class `N3.B` derives from class `N1.N2.A`. The same effect can be obtained by

creating an alias `R` for `N1.N2` and then referencing `R.A`:

C#

```
namespace N3
{
    using R = N1.N2;

    class B : R.A {}
}
```

end example

Within using directives, global attributes and member declarations in a compilation unit or namespace body that contains an *extern_alias_directive*, the identifier introduced by the *extern_alias_directive* can be used to reference the associated namespace.

Example: For example:

C#

```
namespace N1
{
    extern alias N2;

    class B : N2::A {}
}
```

Above, within member declarations in the `N1` namespace, `N2` is an alias for some namespace whose definition is external to the source code of the program. Class `N1.B` derives from class `N2.A`. The same effect can be obtained by creating an alias `A` for `N2.A` and then referencing `A`:

C#

```
namespace N1
{
    extern alias N2;

    using A = N2::A;

    class B : A {}
}
```

end example

An *extern_alias_directive* or *using_alias_directive* makes an alias available within a particular compilation unit or namespace body, but it does not contribute any new members to the underlying declaration space. In other words, an alias directive is not transitive, but, rather, affects only the compilation unit or namespace body in which it occurs.

Example: In the following code

C#

```
namespace N3
{
    extern alias R1;

    using R2 = N1.N2;
}

namespace N3
{
    class B : R1::A, R2.I {} // Error, R1 and R2 unknown
}
```

the scopes of the alias directives that introduce `R1` and `R2` only extend to member declarations in the namespace body in which they are contained, so `R1` and `R2` are unknown in the second namespace declaration. However, placing the alias directives in the containing compilation unit causes the alias to become available within both namespace declarations:

C#

```
extern alias R1;

using R2 = N1.N2;

namespace N3
{
    class B : R1::A, R2.I {}
}

namespace N3
{
    class C : R1::A, R2.I {}
}
```

end example

Each *extern_alias_directive* or *using_alias_directive* in a *compilation_unit* or *namespace_body* contributes a name to the alias declaration space (§7.3) of the immediately enclosing *compilation_unit* or *namespace_body*. The *identifier* of the alias directive shall be unique within the corresponding alias declaration space. The alias identifier need not be unique within the global declaration space or the declaration space of the corresponding namespace.

Example:

```
C#  
  
extern alias A;  
extern alias B;  
  
using A = N1.N2; // Error: alias A already exists  
  
class B {} // Ok
```

The using alias named **A** causes an error since there is already an alias named **A** in the same compilation unit. The class named **B** does not conflict with the extern alias named **B** since these names are added to distinct declaration spaces. The former is added to the global declaration space and the latter is added to the alias declaration space for this compilation unit.

When an alias name matches the name of a member of a namespace, usage of either must be appropriately qualified:

```
C#  
  
namespace N1.N2  
{  
    class B {}  
}  
  
namespace N3  
{  
    class A {}  
    class B : A {}  
}  
  
namespace N3  
{  
    using A = N1.N2;  
    using B = N1.N2.B;  
  
    class W : B {} // Error: B is ambiguous  
    class X : A.B {} // Error: A is ambiguous  
    class Y : A::B {} // Ok: uses N1.N2.B
```

```
class Z : N3.B {} // Ok: uses N3.B
}
```

In the second namespace body for `N3`, unqualified use of `B` results in an error, since `N3` contains a member named `B` and the namespace body that also declares an alias with name `B`; likewise for `A`. The class `N3.B` can be referenced as `N3.B` or `global::N3.B`. The alias `A` can be used in a *qualified-alias-member* (§13.8), such as `A::B`. The alias `B` is essentially useless. It cannot be used in a *qualified_alias_member* since only namespace aliases can be used in a *qualified_alias_member* and `B` aliases a type.

end example

Just like regular members, names introduced by *alias_directives* are hidden by similarly named members in nested scopes.

Example: In the following code

```
C#
using R = N1.N2;

namespace N3
{
    class R {}
    class B: R.A {} // Error, R has no member A
}
```

the reference to `R.A` in the declaration of `B` causes a compile-time error because `R` refers to `N3.R`, not `N1.N2`.

end example

The order in which *extern_alias_directives* are written has no significance. Likewise, the order in which *using_alias_directives* are written has no significance, but all *using_alias_directives* must come after all *extern_alias_directives* in the same compilation unit or namespace body. Resolution of the *namespace_or_type_name* referenced by a *using_alias_directive* is not affected by the *using_alias_directive* itself or by other *using_directives* in the immediately containing compilation unit or namespace body, but may be affected by *extern_alias_directives* in the immediately containing compilation unit or namespace body. In other words, the *namespace_or_type_name* of a *using_alias_directive* is resolved as if the immediately containing compilation unit or

namespace body had no *using_directives* but has the correct set of *extern_alias_directives*.

Example: In the following code

```
C#  
  
namespace N1.N2 {}  
  
namespace N3  
{  
    extern alias E;  
  
    using R1 = E::N; // OK  
    using R2 = N1; // OK  
    using R3 = N1.N2; // OK  
    using R4 = R2.N2; // Error, R2 unknown  
}
```

the last *using_alias_directive* results in a compile-time error because it is not affected by the previous *using_alias_directive*. The first *using_alias_directive* does not result in an error since the scope of the extern alias E includes the *using_alias_directive*.

end example

A *using_alias_directive* can create an alias for any namespace or type, including the namespace within which it appears and any namespace or type nested within that namespace.

Accessing a namespace or type through an alias yields exactly the same result as accessing that namespace or type through its declared name.

Example: Given

```
C#  
  
namespace N1.N2  
{  
    class A {}  
}  
  
namespace N3  
{  
    using R1 = N1;  
    using R2 = N1.N2;  
  
    class B  
    {
```

```

    N1.N2.A a; // refers to N1.N2.A
    R1.N2.A b; // refers to N1.N2.A
    R2.A c; // refers to N1.N2.A
}
}

```

the names `N1.N2.A`, `R1.N2.A`, and `R2.A` are equivalent and all refer to the class declaration whose fully qualified name is `N1.N2.A`.

end example

Although each part of a partial type (§14.2.7) is declared within the same namespace, the parts are typically written within different namespace declarations. Thus, different *extern_alias_directives* and *using_directives* can be present for each part. When interpreting simple names (§11.7.4) within one part, only the *extern_alias_directives* and *using_directives* of the namespace bodies and compilation unit enclosing that part are considered. This may result in the same identifier having different meanings in different parts.

Example:

```

C#

namespace N
{
    using List = System.Collections.ArrayList;

    partial class A
    {
        List x; // x has type System.Collections.ArrayList
    }
}

namespace N
{
    using List = Widgets.LinkedList;

    partial class A
    {
        List y; // y has type Widgets.LinkedList
    }
}

```

end example

Using aliases can name a closed constructed type, but cannot name an unbound generic type declaration without supplying type arguments.

Example:

```
C#  
  
namespace N1  
{  
    class A<T>  
    {  
        class B {}  
    }  
}  
  
namespace N2  
{  
    using W = N1.A;           // Error, cannot name unbound generic type  
    using X = N1.A.B;        // Error, cannot name unbound generic type  
    using Y = N1.A<int>;     // Ok, can name closed constructed type  
    using Z<T> = N1.A<T>;    // Error, using alias cannot have type  
    parameters  
}
```

end example

13.5.3 Using namespace directives

A *using_namespace_directive* imports the types contained in a namespace into the immediately enclosing compilation unit or namespace body, enabling the identifier of each type to be used without qualification.

ANTLR

```
using_namespace_directive  
    : 'using' namespace_name ';' ;
```

Within member declarations in a compilation unit or namespace body that contains a *using_namespace_directive*, the types contained in the given namespace can be referenced directly.

Example:

```
C#  
  
namespace N1.N2  
{  
    class A {}  
}
```

```
namespace N3
{
    using N1.N2;

    class B : A {}
}
```

Above, within member declarations in the `N3` namespace, the type members of `N1.N2` are directly available, and thus class `N3.B` derives from class `N1.N2.A`.

end example

A *using_namespace_directive* imports the types contained in the given namespace, but specifically does not import nested namespaces.

Example: In the following code

```
C#
namespace N1.N2
{
    class A {}
}

namespace N3
{
    using N1;
    class B : N2.A {} // Error, N2 unknown
}
```

the *using_namespace_directive* imports the types contained in `N1`, but not the namespaces nested in `N1`. Thus, the reference to `N2.A` in the declaration of `B` results in a compile-time error because no members named `N2` are in scope.

end example

Unlike a *using_alias_directive*, a *using_namespace_directive* may import types whose identifiers are already defined within the enclosing compilation unit or namespace body. In effect, names imported by a *using_namespace_directive* are hidden by similarly named members in the enclosing compilation unit or namespace body.

Example:

```
C#
```

```

namespace N1.N2
{
    class A {}
    class B {}
}

namespace N3
{
    using N1.N2;
    class A {}
}

```

Here, within member declarations in the `N3` namespace, `A` refers to `N3.A` rather than `N1.N2.A`.

end example

Because names may be ambiguous when more than one imported namespace introduces the same type name, a *using_alias_directive* is useful to disambiguate the reference.

Example: In the following code

```

C#

namespace N1
{
    class A {}
}

namespace N2
{
    class A {}
}

namespace N3
{
    using N1;
    using N2;

    class B : A {} // Error, A is ambiguous
}

```

both `N1` and `N2` contain a member `A`, and because `N3` imports both, referencing `A` in `N3` is a compile-time error. In this situation, the conflict can be resolved either through qualification of references to `A`, or by introducing a *using_alias_directive* that picks a particular `A`. For example:

C#

```
namespace N3
{
    using N1;
    using N2;
    using A = N1.A;

    class B : A {} // A means N1.A
}
```

end example

Furthermore, when more than one namespace or type imported by *using_namespace_directives* or *using_static_directives* in the same compilation unit or namespace body contain types or members by the same name, references to that name as a *simple_name* are considered ambiguous.

Example:

C#

```
namespace N1
{
    class A {}
}

class C
{
    public static int A;
}

namespace N2
{
    using N1;
    using static C;

    class B
    {
        void M()
        {
            A a = new A(); // Ok, A is unambiguous as a type-name
            A.Equals(2);   // Error, A is ambiguous as a simple-name
        }
    }
}
```

N1 contains a type member **A**, and **C** contains a static field **A**, and because **N2** imports both, referencing **A** as a *simple_name* is ambiguous and a compile-time

error.

end example

Like a *using_alias_directive*, a *using_namespace_directive* does not contribute any new members to the underlying declaration space of the compilation unit or namespace, but, rather, affects only the compilation unit or namespace body in which it appears.

The *namespace_name* referenced by a *using_namespace_directive* is resolved in the same way as the *namespace_or_type_name* referenced by a *using_alias_directive*. Thus, *using_namespace_directives* in the same compilation unit or namespace body do not affect each other and can be written in any order.

13.5.4 Using static directives

A *using_static_directive* imports the nested types and static members contained directly in a type declaration into the immediately enclosing compilation unit or namespace body, enabling the identifier of each member and type to be used without qualification.

ANTLR

```
using_static_directive
: 'using' 'static' type_name ';'
;
```

Within member declarations in a compilation unit or namespace body that contains a *using_static_directive*, the accessible nested types and static members (except extension methods) contained directly in the declaration of the given type can be referenced directly.

Example:

C#

```
namespace N1
{
    class A
    {
        public class B {}
        public static B M() => new B();
    }
}

namespace N2
{
    using static N1.A;
```

```

class C
{
    void N()
    {
        B b = M();
    }
}

```

In the preceding code, within member declarations in the `N2` namespace, the static members and nested types of `N1.A` are directly available, and thus the method `N` is able to reference both the `B` and `M` members of `N1.A`.

end example

A `using_static_directive` specifically does not import extension methods directly as static methods, but makes them available for extension method invocation (§11.7.8.3).

Example:

```

C#

namespace N1
{
    static class A
    {
        public static void M(this string s){}
    }
}

namespace N2
{
    using static N1.A;

    class B
    {
        void N()
        {
            M("A");           // Error, M unknown
            "B".M();          // Ok, M known as extension method
            N1.A.M("C");      // Ok, fully qualified
        }
    }
}

```

the `using_static_directive` imports the extension method `M` contained in `N1.A`, but only as an extension method. Thus, the first reference to `M` in the body of `B.N`

results in a compile-time error because no members named `M` are in scope.

end example

A `using_static_directive` only imports members and types declared directly in the given type, not members and types declared in base classes.

Example:

```
C#  
  
namespace N1  
{  
    class A  
    {  
        public static void M(string s){}  
    }  
  
    class B : A  
    {  
        public static void M2(string s){}  
    }  
}  
  
namespace N2  
{  
    using static N1.B;  
  
    class C  
    {  
        void N()  
        {  
            M2("B");    // OK, calls B.M2  
            M("C");    // Error. M unknown  
        }  
    }  
}
```

the `using_static_directive` imports the method `M2` contained in `N1.B`, but does not import the method `M` contained in `N1.A`. Thus, the reference to `M` in the body of `C.N` results in a compile-time error because no members named `M` are in scope. Developers must add a second `using static` directive to specify that the methods in `N1.A` should also be imported.

end example

Ambiguities between multiple *using_namespace_directives* and *using_static_directives* are discussed in §13.5.3.

13.6 Namespace member declarations

A *namespace_member_declaration* is either a *namespace_declaration* (§13.3) or a *type_declaration* (§13.7).

ANTLR

```
namespace_member_declaration
    : namespace_declaration
    | type_declaration
    ;
```

A compilation unit or a namespace body can contain *namespace_member_declarations*, and such declarations contribute new members to the underlying declaration space of the containing compilation unit or namespace body.

13.7 Type declarations

A *type_declaration* is a *class_declaration* (§14.2), a *struct_declaration* (§15.2), an *interface_declaration* (§17.2), an *enum_declaration* (§18.2), or a *delegate_declaration* (§19.2).

ANTLR

```
type_declaration
    : class_declaration
    | struct_declaration
    | interface_declaration
    | enum_declaration
    | delegate_declaration
    ;
```

A *type_declaration* can occur as a top-level declaration in a compilation unit or as a member declaration within a namespace, class, or struct.

When a type declaration for a type `T` occurs as a top-level declaration in a compilation unit, the fully qualified name (§7.8.2) of the type declaration is the same as the unqualified name of the declaration (§7.8.2). When a type declaration for a type `T` occurs within a namespace, class, or struct declaration, the fully qualified name (§7.8.3)

of the type declaration is `S.N`, where `S` is the fully qualified name of the containing namespace, class, or struct declaration, and `N` is the unqualified name of the declaration.

A type declared within a class or struct is called a nested type (§14.3.9).

The permitted access modifiers and the default access for a type declaration depend on the context in which the declaration takes place (§7.5.2):

- Types declared in compilation units or namespaces can have `public` or `internal` access. The default is `internal` access.
- Types declared in classes can have `public`, `protected internal`, `protected`, `private protected`, `internal`, or `private` access. The default is `private` access.
- Types declared in structs can have `public`, `internal`, or `private` access. The default is `private` access.

13.8 Qualified alias member

13.8.1 General

The *namespace alias qualifier* `::` makes it possible to guarantee that type name lookups are unaffected by the introduction of new types and members. The namespace alias qualifier always appears between two identifiers referred to as the left-hand and right-hand identifiers. Unlike the regular `.` qualifier, the left-hand identifier of the `::` qualifier is looked up only as an extern or using alias.

A *qualified_alias_member* provides explicit access to the global namespace and to extern or using aliases that are potentially hidden by other entities.

ANTLR

```
qualified_alias_member
    : identifier '::' identifier type_argument_list?
    ;
```

A *qualified_alias_member* can be used as a *namespace_or_type_name* (§7.8) or as the left operand in a *member_access* (§11.7.6).

A *qualified_alias_member* consists of two identifiers, referred to as the left-hand and right-hand identifiers, separated by the `::` token and optionally followed by a *type_argument_list*. When the left-hand identifier is global then the global namespace is searched for the right-hand identifier. For any other left-hand identifier, that identifier is looked up as an extern or using alias (§13.4 and §13.5.2). A compile-time error occurs if

there is no such alias or the alias references a type. If the alias references a namespace then that namespace is searched for the right-hand identifier.

A *qualified_alias_member* has one of two forms:

- $N::I\langle A_1, \dots, A_e \rangle$, where N and I represent identifiers, and $\langle A_1, \dots, A_e \rangle$ is a type argument list. (e is always at least one.)
- $N::I$, where N and I represent identifiers. (In this case, e is considered to be zero.)

Using this notation, the meaning of a *qualified_alias_member* is determined as follows:

- If N is the identifier `global`, then the global namespace is searched for I :
 - If the global namespace contains a namespace named I and e is zero, then the *qualified_alias_member* refers to that namespace.
 - Otherwise, if the global namespace contains a non-generic type named I and e is zero, then the *qualified_alias_member* refers to that type.
 - Otherwise, if the global namespace contains a type named I that has e type parameters, then the *qualified_alias_member* refers to that type constructed with the given type arguments.
 - Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.
- Otherwise, starting with the namespace declaration (§13.3) immediately containing the *qualified_alias_member* (if any), continuing with each enclosing namespace declaration (if any), and ending with the compilation unit containing the *qualified_alias_member*, the following steps are evaluated until an entity is located:
 - If the namespace declaration or compilation unit contains a *using_alias_directive* that associates N with a type, then the *qualified_alias_member* is undefined and a compile-time error occurs.
 - Otherwise, if the namespace declaration or compilation unit contains an *extern_alias_directive* or *using_alias_directive* that associates N with a namespace, then:
 - If the namespace associated with N contains a namespace named I and e is zero, then the *qualified_alias_member* refers to that namespace.
 - Otherwise, if the namespace associated with N contains a non-generic type named I and e is zero, then the *qualified_alias_member* refers to that type.
 - Otherwise, if the namespace associated with N contains a type named I that has e type parameters, then the *qualified_alias_member* refers to that type constructed with the given type arguments.
 - Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.

- Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.

Example: In the code:

```
C#  
  
using S = System.Net.Sockets;  
  
class A  
{  
    public static int x;  
}  
  
class C  
{  
    public void F(int A, object S)  
    {  
        // Use global::A.x instead of A.x  
        global::A.x += A;  
        // Use S::Socket instead of S.Socket  
        S::Socket s = S as S::Socket;  
    }  
}
```

the class `A` is referenced with `global::A` and the type `System.Net.Sockets.Socket` is referenced with `S::Socket`. Using `A.x` and `S.Socket` instead would have caused compile-time errors because `A` and `S` would have resolved to the parameters.

end example

Note: The identifier `global` has special meaning only when used as the left-hand identifier of a *qualified_alias_name*. It is not a keyword and it is not itself an alias; it is a contextual keyword (§6.4.4). In the code:

```
C#  
  
class A { }  
  
class C  
{  
    global.A x; // Error: global is not defined  
    global::A y; // Valid: References A in the global namespace  
}
```

using `global.A` causes a compile-time error since there is no entity named `global` in scope. If some entity named `global` were in scope, then `global` in `global.A` would

have resolved to that entity.

Using `global` as the left-hand identifier of a *qualified_alias_member* always causes a lookup in the `global` namespace, even if there is a using alias named `global`. In the code:

```
C#  
  
using global = MyGlobalTypes;  
  
class A { }  
  
class C  
{  
    global.A x; // Valid: References MyGlobalTypes.A  
    global::A y; // Valid: References A in the global namespace  
}
```

`global.A` resolves to `MyGlobalTypes.A` and `global::A` resolves to class `A` in the global namespace.

end note

13.8.2 Uniqueness of aliases

Each compilation unit and namespace body has a separate declaration space for extern aliases and using aliases. Thus, while the name of an extern alias or using alias shall be unique within the set of extern aliases and using aliases declared in the immediately containing compilation unit or namespace body, an alias is permitted to have the same name as a type or namespace as long as it is used only with the `::` qualifier.

Example: In the following:

```
C#  
  
namespace N  
{  
    public class A {}  
    public class B {}  
}  
  
namespace N  
{  
    using A = System.IO;  
  
    class X  
    {
```

```
A.Stream s1; // Error, A is ambiguous
A::Stream s2; // Ok
    }
}
```

the name `A` has two possible meanings in the second namespace body because both the class `A` and the using alias `A` are in scope. For this reason, use of `A` in the qualified name `A.Stream` is ambiguous and causes a compile-time error to occur. However, use of `A` with the `::` qualifier is not an error because `A` is looked up only as a namespace alias.

end example

14 Classes

Article • 2023-01-17 • 166 minutes to read

14.1 General

A class is a data structure that may contain data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, finalizers, and static constructors), and nested types. Class types support inheritance, a mechanism whereby a *derived class* can extend and specialize a *base class*.

14.2 Class declarations

14.2.1 General

A *class_declaration* is a *type_declaration* (§13.7) that declares a new class.

ANTLR

```
class_declaration
: attributes? class_modifier* 'partial'? 'class' identifier
  type_parameter_list? class_base? type_parameter_constraints_clause*
  class_body ';'
;
```

A *class_declaration* consists of an optional set of *attributes* (§21), followed by an optional set of *class_modifiers* (§14.2.2), followed by an optional `partial` modifier (§14.2.7), followed by the keyword `class` and an *identifier* that names the class, followed by an optional *type_parameter_list* (§14.2.3), followed by an optional *class_base* specification (§14.2.4), followed by an optional set of *type_parameter_constraints_clauses* (§14.2.5), followed by a *class_body* (§14.2.6), optionally followed by a semicolon.

A class declaration shall not supply a *type_parameter_constraints_clauses* unless it also supplies a *type_parameter_list*.

A class declaration that supplies a *type_parameter_list* is a generic class declaration. Additionally, any class nested inside a generic class declaration or a generic struct declaration is itself a generic class declaration, since type arguments for the containing type shall be supplied to create a constructed type (§8.4).

14.2.2 Class modifiers

14.2.2.1 General

A *class_declaration* may optionally include a sequence of class modifiers:

ANTLR

```
class_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'abstract'
| 'sealed'
| 'static'
| unsafe_modifier // unsafe code support
;
```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

It is a compile-time error for the same modifier to appear multiple times in a class declaration.

The `new` modifier is permitted on nested classes. It specifies that the class hides an inherited member by the same name, as described in §14.3.5. It is a compile-time error for the `new` modifier to appear on a class declaration that is not a nested class declaration.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the class. Depending on the context in which the class declaration occurs, some of these modifiers might not be permitted (§7.5.2).

When a partial type declaration (§14.2.7) includes an accessibility specification (via the `public`, `protected`, `internal`, and `private` modifiers), that specification shall agree with all other parts that include an accessibility specification. If no part of a partial type includes an accessibility specification, the type is given the appropriate default accessibility (§7.5.2).

The `abstract`, `sealed`, and `static` modifiers are discussed in the following subclasses.

14.2.2.2 Abstract classes

The `abstract` modifier is used to indicate that a class is incomplete and that it is intended to be used only as a base class. An **abstract class** differs from a **non-abstract class** in the following ways:

- An abstract class cannot be instantiated directly, and it is a compile-time error to use the `new` operator on an abstract class. While it is possible to have variables and values whose compile-time types are abstract, such variables and values will necessarily either be `null` or contain references to instances of non-abstract classes derived from the abstract types.
- An abstract class is permitted (but not required) to contain abstract members.
- An abstract class cannot be sealed.

When a non-abstract class is derived from an abstract class, the non-abstract class shall include actual implementations of all inherited abstract members, thereby overriding those abstract members.

Example: In the following code

```
C#  
  
abstract class A  
{  
    public abstract void F();  
}  
  
abstract class B : A  
{  
    public void G() {}  
}  
  
class C : B  
{  
    public override void F()  
    {  
        // Actual implementation of F  
    }  
}
```

the abstract class `A` introduces an abstract method `F`. Class `B` introduces an additional method `G`, but since it doesn't provide an implementation of `F`, `B` shall also be declared abstract. Class `C` overrides `F` and provides an actual implementation. Since there are no abstract members in `C`, `C` is permitted (but not required) to be non-abstract.

end example

If one or more parts of a partial type declaration (§14.2.7) of a class include the `abstract` modifier, the class is abstract. Otherwise, the class is non-abstract.

14.2.2.3 Sealed classes

The `sealed` modifier is used to prevent derivation from a class. A compile-time error occurs if a sealed class is specified as the base class of another class.

A sealed class cannot also be an abstract class.

Note: The `sealed` modifier is primarily used to prevent unintended derivation, but it also enables certain run-time optimizations. In particular, because a sealed class is known to never have any derived classes, it is possible to transform virtual function member invocations on sealed class instances into non-virtual invocations. *end note*

If one or more parts of a partial type declaration (§14.2.7) of a class include the `sealed` modifier, the class is sealed. Otherwise, the class is unsealed.

14.2.2.4 Static classes

14.2.2.4.1 General

The `static` modifier is used to mark the class being declared as a **static class**. A static class shall not be instantiated, shall not be used as a type and shall contain only static members. Only a static class can contain declarations of extension methods (§14.6.10).

A static class declaration is subject to the following restrictions:

- A static class shall not include a `sealed` or `abstract` modifier. (However, since a static class cannot be instantiated or derived from, it behaves as if it was both sealed and abstract.)
- A static class shall not include a `class_base` specification (§14.2.4) and cannot explicitly specify a base class or a list of implemented interfaces. A static class implicitly inherits from type `object`.
- A static class shall only contain static members (§14.3.8).

Note: All constants and nested types are classified as static members. *end note*

- A static class shall not have members with `protected`, `private protected`, or `protected internal` declared accessibility.

It is a compile-time error to violate any of these restrictions.

A static class has no instance constructors. It is not possible to declare an instance constructor in a static class, and no default instance constructor (§14.11.5) is provided for a static class.

The members of a static class are not automatically static, and the member declarations shall explicitly include a `static` modifier (except for constants and nested types). When a class is nested within a static outer class, the nested class is not a static class unless it explicitly includes a `static` modifier.

If one or more parts of a partial type declaration (§14.2.7) of a class include the `static` modifier, the class is static. Otherwise, the class is not static.

14.2.2.4.2 Referencing static class types

A *namespace_or_type_name* (§7.8) is permitted to reference a static class if

- The *namespace_or_type_name* is the `T` in a *namespace_or_type_name* of the form `T.I`, or
- The *namespace_or_type_name* is the `T` in a *typeof_expression* (§11.7.16) of the form `typeof(T)`.

A *primary_expression* (§11.7) is permitted to reference a static class if

- The *primary_expression* is the `E` in a *member_access* (§11.7.6) of the form `E.I`.

In any other context, it is a compile-time error to reference a static class.

Note: For example, it is an error for a static class to be used as a base class, a constituent type (§14.3.7) of a member, a generic type argument, or a type parameter constraint. Likewise, a static class cannot be used in an array type, a pointer type, a new expression, a cast expression, an `is` expression, an `as` expression, a `sizeof` expression, or a default value expression. *end note*

14.2.3 Type parameters

A type parameter is a simple identifier that denotes a placeholder for a type argument supplied to create a constructed type. By contrast, a type argument (§8.4.2) is the type that is substituted for the type parameter when a constructed type is created.

```

type_parameter_list
    : '<' type_parameters '>'
    ;

type_parameters
    : attributes? type_parameter
    | type_parameters ',' attributes? type_parameter
    ;

```

type_parameter is defined in §8.5.

Each type parameter in a class declaration defines a name in the declaration space (§7.3) of that class. Thus, it cannot have the same name as another type parameter of that class or a member declared in that class. A type parameter cannot have the same name as the type itself.

Two partial generic type declarations (in the same program) contribute to the same unbound generic type if they have the same fully qualified name (which includes a *generic_dimension_specifier* (§11.7.16) for the number of type parameters) (§7.8.3). Two such partial type declarations shall specify the same name for each type parameter, in order.

14.2.4 Class base specification

14.2.4.1 General

A class declaration may include a *class_base* specification, which defines the direct base class of the class and the interfaces (§17) directly implemented by the class.

```

ANTLR

class_base
    : ':' class_type
    | ':' interface_type_list
    | ':' class_type ',' interface_type_list
    ;

interface_type_list
    : interface_type (',' interface_type)*
    ;

```

14.2.4.2 Base classes

When a *class_type* is included in the *class_base*, it specifies the direct base class of the class being declared. If a non-partial class declaration has no *class_base*, or if the *class_base* lists only interface types, the direct base class is assumed to be `object`. When a partial class declaration includes a base class specification, that base class specification shall reference the same type as all other parts of that partial type that include a base class specification. If no part of a partial class includes a base class specification, the base class is `object`. A class inherits members from its direct base class, as described in §14.3.4.

Example: In the following code

```
C#  
  
class A {}  
class B : A {}
```

Class `A` is said to be the direct base class of `B`, and `B` is said to be derived from `A`. Since `A` does not explicitly specify a direct base class, its direct base class is implicitly `object`.

end example

For a constructed class type, including a nested type declared within a generic type declaration (§14.3.9.7), if a base class is specified in the generic class declaration, the base class of the constructed type is obtained by substituting, for each *type_parameter* in the base class declaration, the corresponding *type_argument* of the constructed type.

Example: Given the generic class declarations

```
C#  
  
class B<U,V> {...}  
class G<T> : B<string,T[]> {...}
```

the base class of the constructed type `G<int>` would be `B<string,int[]>`.

end example

The base class specified in a class declaration can be a constructed class type (§8.4). A base class cannot be a type parameter on its own (§8.5), though it can involve the type parameters that are in scope.

Example:

```
C#  
  
class Base<T> {}  
  
// Valid, non-constructed class with constructed base class  
class Extend1 : Base<int> {}  
  
// Error, type parameter used as base class  
class Extend2<V> : V {}  
  
// Valid, type parameter used as type argument for base class  
class Extend3<V> : Base<V> {}
```

end example

The direct base class of a class type shall be at least as accessible as the class type itself (§7.5.5). For example, it is a compile-time error for a public class to derive from a private or internal class.

The direct base class of a class type shall not be any of the following types:

`System.Array`, `System.Delegate`, `System.Enum`, or `System.ValueType`. Furthermore, a generic class declaration shall not use `System.Attribute` as a direct or indirect base class (§21.2.1).

In determining the meaning of the direct base class specification `A` of a class `B`, the direct base class of `B` is temporarily assumed to be `object`, which ensures that the meaning of a base class specification cannot recursively depend on itself.

Example: The following

```
C#  
  
class X<T>  
{  
    public class Y{}  
}  
  
class Z : X<Z.Y> {}
```

is in error since in the base class specification `X<Z.Y>` the direct base class of `Z` is considered to be `object`, and hence (by the rules of §7.8) `Z` is not considered to have a member `Y`.

end example

The base classes of a class are the direct base class and its base classes. In other words, the set of base classes is the transitive closure of the direct base class relationship.

Example: In the following:

```
C#  
  
class A {...}  
class B<T> : A {...}  
class C<T> : B<IComparable<T>> {...}  
class D<T> : C<T[]> {...}
```

the base classes of `D<int>` are `C<int[]>`, `B<IComparable<int[]>>`, `A`, and `object`.

end example

Except for class `object`, every class has exactly one direct base class. The `object` class has no direct base class and is the ultimate base class of all other classes.

It is a compile-time error for a class to depend on itself. For the purpose of this rule, a class **directly depends on** its direct base class (if any) and *directly depends on* the nearest enclosing class within which it is nested (if any). Given this definition, the complete set of classes upon which a class depends is the transitive closure of the *directly depends on* relationship.

Example: The example

```
C#  
  
class A : A {}
```

is erroneous because the class depends on itself. Likewise, the example

```
C#  
  
class A : B {}  
class B : C {}  
class C : A {}
```

is in error because the classes circularly depend on themselves. Finally, the example

```
C#  
  
class A : B.C {}  
class B : A
```

```
{  
    public class C {}  
}
```

results in a compile-time error because A depends on B.C (its direct base class), which depends on B (its immediately enclosing class), which circularly depends on A.

end example

A class does not depend on the classes that are nested within it.

Example: In the following code

```
C#  
  
class A  
{  
    class B : A {}  
}
```

B depends on A (because A is both its direct base class and its immediately enclosing class), but A does not depend on B (since B is neither a base class nor an enclosing class of A). Thus, the example is valid.

end example

It is not possible to derive from a sealed class.

Example: In the following code

```
C#  
  
sealed class A {}  
class B : A {} // Error, cannot derive from a sealed class
```

Class B is in error because it attempts to derive from the sealed class A.

end example

14.2.4.3 Interface implementations

A *class_base* specification may include a list of interface types, in which case the class is said to implement the given interface types. For a constructed class type, including a nested type declared within a generic type declaration (§14.3.9.7), each implemented interface type is obtained by substituting, for each *type_parameter* in the given interface, the corresponding *type_argument* of the constructed type.

The set of interfaces for a type declared in multiple parts (§14.2.7) is the union of the interfaces specified on each part. A particular interface can only be named once on each part, but multiple parts can name the same base interface(s). There shall only be one implementation of each member of any given interface.

Example: In the following:

```
C#  
  
partial class C : IA, IB {...}  
partial class C : IC {...}  
partial class C : IA, IB {...}
```

the set of base interfaces for class `C` is `IA`, `IB`, and `IC`.

end example

Typically, each part provides an implementation of the interface(s) declared on that part; however, this is not a requirement. A part can provide the implementation for an interface declared on a different part.

Example:

```
C#  
  
partial class X  
{  
    int IComparable.CompareTo(object o) {...}  
}  
  
partial class X : IComparable  
{  
    ...  
}
```

end example

The base interfaces specified in a class declaration can be constructed interface types (§8.4, §17.2). A base interface cannot be a type parameter on its own, though it can

involve the type parameters that are in scope.

Example: The following code illustrates how a class can implement and extend constructed types:

```
C#  
  
class C<U, V> {}  
interface I1<V> {}  
class D : C<string, int>, I1<string> {}  
class E<T> : C<int, T>, I1<T> {}
```

end example

Interface implementations are discussed further in [§17.6](#).

14.2.5 Type parameter constraints

Generic type and method declarations can optionally specify type parameter constraints by including *type_parameter_constraints_clauses*.

```
ANTLR
```

```
type_parameter_constraints_clauses  
  : type_parameter_constraints_clause  
  | type_parameter_constraints_clauses type_parameter_constraints_clause  
  ;  
  
type_parameter_constraints_clause  
  : 'where' type_parameter ':' type_parameter_constraints  
  ;  
  
type_parameter_constraints  
  : primary_constraint  
  | secondary_constraints  
  | constructor_constraint  
  | primary_constraint ',' secondary_constraints  
  | primary_constraint ',' constructor_constraint  
  | secondary_constraints ',' constructor_constraint  
  | primary_constraint ',' secondary_constraints ','  
constructor_constraint  
  ;  
  
primary_constraint  
  : class_type  
  | 'class'  
  | 'struct'  
  ;
```

```

secondary_constraints
  : interface_type
  | type_parameter
  | secondary_constraints ',' interface_type
  | secondary_constraints ',' type_parameter
  ;

constructor_constraint
  : 'new' '(' ')'
  ;

```

Each *type_parameter_constraints_clause* consists of the token `where`, followed by the name of a type parameter, followed by a colon and the list of constraints for that type parameter. There can be at most one `where` clause for each type parameter, and the `where` clauses can be listed in any order. Like the `get` and `set` tokens in a property accessor, the `where` token is not a keyword.

The list of constraints given in a `where` clause can include any of the following components, in this order: a single primary constraint, one or more secondary constraints, and the constructor constraint, `new()`.

A primary constraint can be a class type or the **reference type constraint** `class` or the **value type constraint** `struct`. A secondary constraint can be a *type_parameter* or *interface_type*.

The reference type constraint specifies that a type argument used for the type parameter shall be a reference type. All class types, interface types, delegate types, array types, and type parameters known to be a reference type (as defined below) satisfy this constraint.

The value type constraint specifies that a type argument used for the type parameter shall be a non-nullable value type. All non-nullable struct types, enum types, and type parameters having the value type constraint satisfy this constraint. Note that although classified as a value type, a nullable value type (§8.3.11) does not satisfy the value type constraint. A type parameter having the value type constraint shall not also have the *constructor_constraint*, although it may be used as a type argument for another type parameter with a *constructor_constraint*.

Note: The `System.Nullable<T>` type specifies the non-nullable value type constraint for `T`. Thus, recursively constructed types of the forms `T??` and `Nullable<Nullable<T>>` are prohibited. *end note*

Pointer types are never allowed to be type arguments and are not considered to satisfy either the reference type or value type constraints.

If a constraint is a class type, an interface type, or a type parameter, that type specifies a minimal “base type” that every type argument used for that type parameter shall support. Whenever a constructed type or generic method is used, the type argument is checked against the constraints on the type parameter at compile-time. The type argument supplied shall satisfy the conditions described in §8.4.5.

A *class_type* constraint shall satisfy the following rules:

- The type shall be a class type.
- The type shall not be `sealed`.
- The type shall not be one of the following types: `System.Array`, `System.Delegate`, `System.Enum`, or `System.ValueType`.
- The type shall not be `object`.
- At most one constraint for a given type parameter may be a class type.

A type specified as an *interface_type* constraint shall satisfy the following rules:

- The type shall be an interface type.
- A type shall not be specified more than once in a given `where` clause.

In either case, the constraint may involve any of the type parameters of the associated type or method declaration as part of a constructed type, and may involve the type being declared.

Any class or interface type specified as a type parameter constraint shall be at least as accessible (§7.5.5) as the generic type or method being declared.

A type specified as a *type_parameter* constraint shall satisfy the following rules:

- The type shall be a type parameter.
- A type shall not be specified more than once in a given `where` clause.

In addition there shall be no cycles in the dependency graph of type parameters, where dependency is a transitive relation defined by:

- If a type parameter `T` is used as a constraint for type parameter `S` then `S` **depends on** `T`.
- If a type parameter `S` depends on a type parameter `T` and `T` depends on a type parameter `U` then `S` **depends on** `U`.

Given this relation, it is a compile-time error for a type parameter to depend on itself (directly or indirectly).

Any constraints shall be consistent among dependent type parameters. If type parameter `S` depends on type parameter `T` then:

- `T` shall not have the value type constraint. Otherwise, `T` is effectively sealed so `S` would be forced to be the same type as `T`, eliminating the need for two type parameters.
- If `S` has the value type constraint then `T` shall not have a *class_type* constraint.
- If `S` has a *class_type* constraint `A` and `T` has a *class_type* constraint `B` then there shall be an identity conversion or implicit reference conversion from `A` to `B` or an implicit reference conversion from `B` to `A`.
- If `S` also depends on type parameter `U` and `U` has a *class_type* constraint `A` and `T` has a *class_type* constraint `B` then there shall be an identity conversion or implicit reference conversion from `A` to `B` or an implicit reference conversion from `B` to `A`.

It is valid for `S` to have the value type constraint and `T` to have the reference type constraint. Effectively this limits `T` to the types `System.Object`, `System.ValueType`, `System.Enum`, and any interface type.

If the `where` clause for a type parameter includes a constructor constraint (which has the form `new()`), it is possible to use the `new` operator to create instances of the type (§11.7.15.2). Any type argument used for a type parameter with a constructor constraint shall be a value type, a non-abstract class having a public parameterless constructor, or a type parameter having the value type constraint or constructor constraint.

It is a compile-time error for *type_parameter_constraints* having a *primary_constraint* of `struct` to also have a *constructor_constraint*.

Example: The following are examples of constraints:

```
C#  
  
interface IPrintable  
{  
    void Print();  
}  
  
interface IComparable<T>  
{  
    int CompareTo(T value);  
}  
  
interface IKeyProvider<T>
```

```

{
    T GetKey();
}

class Printer<T> where T : IPrintable {...}
class SortedList<T> where T : IComparable<T> {...}

class Dictionary<K,V>
    where K : IComparable<K>
    where V : IPrintable, IKeyProvider<K>, new()
{
    ...
}

```

The following example is in error because it causes a circularity in the dependency graph of the type parameters:

```

C#

class Circular<S,T>
    where S: T
    where T: S // Error, circularity in dependency graph
{
    ...
}

```

The following examples illustrate additional invalid situations:

```

C#

class Sealed<S,T>
    where S : T
    where T : struct // Error, `T` is sealed
{
    ...
}

class A {...}
class B {...}

class Incompat<S,T>
    where S : A, T
    where T : B // Error, incompatible class-type constraints
{
    ...
}

class StructWithClass<S,T,U>
    where S : struct, T
    where T : U
    where U : A // Error, A incompatible with struct

```

```
{  
    ...  
}
```

end example

The **dynamic erasure** of a type C is type C_x constructed as follows:

- If C is a nested type `Outer.Inner` then C_x is a nested type `Outer_x.Inner_x`.
- If C is a constructed type `G<A1, ..., An>` with type arguments `A1, ..., An` then C_x is the constructed type `G<A1_x, ..., An_x>`.
- If C is an array type `E[]` then C_x is the array type `E_x[]`.
- If C is a pointer type `E*` then C_x is the pointer type `E_x*`.
- If C is dynamic then C_x is `object`.
- Otherwise, C_x is C .

The **effective base class** of a type parameter T is defined as follows:

Let R be a set of types such that:

- For each constraint of T that is a type parameter, R contains its effective base class.
- For each constraint of T that is a struct type, R contains `System.ValueType`.
- For each constraint of T that is an enumeration type, R contains `System.Enum`.
- For each constraint of T that is a delegate type, R contains its dynamic erasure.
- For each constraint of T that is an array type, R contains `System.Array`.
- For each constraint of T that is a class type, R contains its dynamic erasure.

Then

- If T has the value type constraint, its effective base class is `System.ValueType`.
- Otherwise, if R is empty then the effective base class is `object`.
- Otherwise, the effective base class of T is the most-encompassed type (§10.5.3) of set R . If the set has no encompassed type, the effective base class of T is `object`.

The consistency rules ensure that the most-encompassed type exists.

If the type parameter is a method type parameter whose constraints are inherited from the base method the effective base class is calculated after type substitution.

These rules ensure that the effective base class is always a *class_type*.

The **effective interface set** of a type parameter T is defined as follows:

- If `T` has no *secondary_constraints*, its effective interface set is empty.
- If `T` has *interface_type* constraints but no *type_parameter* constraints, its effective interface set is the set of dynamic erasures of its *interface_type* constraints.
- If `T` has no *interface_type* constraints but has *type_parameter* constraints, its effective interface set is the union of the effective interface sets of its *type_parameter* constraints.
- If `T` has both *interface_type* constraints and *type_parameter* constraints, its effective interface set is the union of the set of dynamic erasures of its *interface_type* constraints and the effective interface sets of its *type_parameter* constraints.

A type parameter is *known to be a reference type* if it has the reference type constraint or its effective base class is not `object` or `System.ValueType`.

Values of a constrained type parameter type can be used to access the instance members implied by the constraints.

Example: In the following:

```
C#
interface IPrintable
{
    void Print();
}

class Printer<T> where T : IPrintable
{
    void PrintOne(T x) => x.Print();
}
```

the methods of `IPrintable` can be invoked directly on `x` because `T` is constrained to always implement `IPrintable`.

end example

When a partial generic type declaration includes constraints, the constraints shall agree with all other parts that include constraints. Specifically, each part that includes constraints shall have constraints for the same set of type parameters, and for each type parameter, the sets of primary, secondary, and constructor constraints shall be equivalent. Two sets of constraints are equivalent if they contain the same members. If no part of a partial generic type specifies type parameter constraints, the type parameters are considered unconstrained.

Example:

```
C#  
  
partial class Map<K,V>  
    where K : IComparable<K>  
    where V : IKeyProvider<K>, new()  
{  
    ...  
}  
  
partial class Map<K,V>  
    where V : IKeyProvider<K>, new()  
    where K : IComparable<K>  
{  
    ...  
}  
  
partial class Map<K,V>  
{  
    ...  
}
```

is correct because those parts that include constraints (the first two) effectively specify the same set of primary, secondary, and constructor constraints for the same set of type parameters, respectively.

end example

14.2.6 Class body

The *class_body* of a class defines the members of that class.

```
ANTLR
```

```
class_body  
    : '{' class_member_declaration* '}'  
    ;
```

14.2.7 Partial declarations

The modifier `partial` is used when defining a class, struct, or interface type in multiple parts. The `partial` modifier is a contextual keyword (§6.4.4) and only has special meaning immediately before one of the keywords `class`, `struct`, or `interface`.

Each part of a *partial type* declaration shall include a `partial` modifier and shall be declared in the same namespace or containing type as the other parts. The `partial` modifier indicates that additional parts of the type declaration might exist elsewhere, but the existence of such additional parts is not a requirement; it is valid for the only declaration of a type to include the `partial` modifier.

All parts of a partial type shall be compiled together such that the parts can be merged at compile-time. Partial types specifically do not allow already compiled types to be extended.

Nested types can be declared in multiple parts by using the `partial` modifier. Typically, the containing type is declared using `partial` as well, and each part of the nested type is declared in a different part of the containing type.

Example: The following partial class is implemented in two parts, which reside in different compilation units. The first part is machine generated by a database-mapping tool while the second part is manually authored:

C#

```
public partial class Customer
{
    private int id;
    private string name;
    private string address;
    private List<Order> orders;

    public Customer()
    {
        ...
    }
}

public partial class Customer
{
    public void SubmitOrder(Order orderSubmitted) =>
orders.Add(orderSubmitted);

    public bool HasOutstandingOrders() => orders.Count > 0;
}
```

When the two parts above are compiled together, the resulting code behaves as if the class had been written as a single unit, as follows:

C#

```

public class Customer
{
    private int id;
    private string name;
    private string address;
    private List<Order> orders;

    public Customer()
    {
        ...
    }

    public void SubmitOrder(Order orderSubmitted) =>
orders.Add(orderSubmitted);

    public bool HasOutstandingOrders() => orders.Count > 0;
}

```

end example

The handling of attributes specified on the type or type parameters of different parts of a partial declaration is discussed in [§21.3](#).

14.3 Class members

14.3.1 General

The members of a class consist of the members introduced by its *class_member_declarations* and the members inherited from the direct base class.

ANTLR

```

class_member_declaration
: constant_declaration
| field_declaration
| method_declaration
| property_declaration
| event_declaration
| indexer_declaration
| operator_declaration
| constructor_declaration
| finalizer_declaration
| static_constructor_declaration
| type_declaration
;

```

The members of a class are divided into the following categories:

- Constants, which represent constant values associated with the class (§14.4).
- Fields, which are the variables of the class (§14.5).
- Methods, which implement the computations and actions that can be performed by the class (§14.6).
- Properties, which define named characteristics and the actions associated with reading and writing those characteristics (§14.7).
- Events, which define notifications that can be generated by the class (§14.8).
- Indexers, which permit instances of the class to be indexed in the same way (syntactically) as arrays (§14.9).
- Operators, which define the expression operators that can be applied to instances of the class (§14.10).
- Instance constructors, which implement the actions required to initialize instances of the class (§14.11)
- Finalizers, which implement the actions to be performed before instances of the class are permanently discarded (§14.13).
- Static constructors, which implement the actions required to initialize the class itself (§14.12).
- Types, which represent the types that are local to the class (§13.7).

A *class_declaration* creates a new declaration space (§7.3), and the *type_parameters* and the *class_member_declarations* immediately contained by the *class_declaration* introduce new members into this declaration space. The following rules apply to *class_member_declarations*:

- Instance constructors, finalizers, and static constructors shall have the same name as the immediately enclosing class. All other members shall have names that differ from the name of the immediately enclosing class.
- The name of a type parameter in the *type_parameter_list* of a class declaration shall differ from the names of all other type parameters in the same *type_parameter_list* and shall differ from the name of the class and the names of all members of the class.
- The name of a type shall differ from the names of all non-type members declared in the same class. If two or more type declarations share the same fully qualified name, the declarations shall have the `partial` modifier (§14.2.7) and these declarations combine to define a single type.

Note: Since the fully qualified name of a type declaration encodes the number of type parameters, two distinct types may share the same name as long as they have different number of type parameters. *end note*

- The name of a constant, field, property, or event shall differ from the names of all other members declared in the same class.
- The name of a method shall differ from the names of all other non-methods declared in the same class. In addition, the signature (§7.6) of a method shall differ from the signatures of all other methods declared in the same class, and two methods declared in the same class shall not have signatures that differ solely by `ref` and `out`.
- The signature of an instance constructor shall differ from the signatures of all other instance constructors declared in the same class, and two constructors declared in the same class shall not have signatures that differ solely by `ref` and `out`.
- The signature of an indexer shall differ from the signatures of all other indexers declared in the same class.
- The signature of an operator shall differ from the signatures of all other operators declared in the same class.

The inherited members of a class (§14.3.4) are not part of the declaration space of a class.

Note: Thus, a derived class is allowed to declare a member with the same name or signature as an inherited member (which in effect hides the inherited member). *end note*

The set of members of a type declared in multiple parts (§14.2.7) is the union of the members declared in each part. The bodies of all parts of the type declaration share the same declaration space (§7.3), and the scope of each member (§7.7) extends to the bodies of all the parts. The accessibility domain of any member always includes all the parts of the enclosing type; a private member declared in one part is freely accessible from another part. It is a compile-time error to declare the same member in more than one part of the type, unless that member is a type having the `partial` modifier.

Example:

```
C#  
  
partial class A  
{  
    int x;           // Error, cannot declare x more than once  
  
    partial class Inner // Ok, Inner is a partial type  
    {  
        int y;  
    }  
}
```

```

    }
}

partial class A
{
    int x;           // Error, cannot declare x more than once

    partial class Inner // Ok, Inner is a partial type
    {
        int z;
    }
}

```

end example

Field initialization order can be significant within C# code, and some guarantees are provided, as defined in §14.5.6.1. Otherwise, the ordering of members within a type is rarely significant, but may be significant when interfacing with other languages and environments. In these cases, the ordering of members within a type declared in multiple parts is undefined.

14.3.2 The instance type

Each class declaration has an associated *instance type*. For a generic class declaration, the instance type is formed by creating a constructed type (§8.4) from the type declaration, with each of the supplied type arguments being the corresponding type parameter. Since the instance type uses the type parameters, it can only be used where the type parameters are in scope; that is, inside the class declaration. The instance type is the type of `this` for code written inside the class declaration. For non-generic classes, the instance type is simply the declared class.

Example: The following shows several class declarations along with their instance types:

```

C#

class A<T>           // instance type: A<T>
{
    class B {}       // instance type: A<T>.B
    class C<U> {}    // instance type: A<T>.C<U>
}
class D {}          // instance type: D

```

end example

14.3.3 Members of constructed types

The non-inherited members of a constructed type are obtained by substituting, for each *type_parameter* in the member declaration, the corresponding *type_argument* of the constructed type. The substitution process is based on the semantic meaning of type declarations, and is not simply textual substitution.

Example: Given the generic class declaration

```
C#  
  
class Gen<T,U>  
{  
    public T[,] a;  
    public void G(int i, T t, Gen<U,T> gt) {...}  
    public U Prop { get {...} set {...} }  
    public int H(double d) {...}  
}
```

the constructed type `Gen<int[],IComparable<string>>` has the following members:

```
C#  
  
public int[,] a;  
public void G(int i, int[] t, Gen<IComparable<string>,int[]> gt) {...}  
public IComparable<string> Prop { get {...} set {...} }  
public int H(double d) {...}
```

The type of the member `a` in the generic class declaration `Gen` is “two-dimensional array of `T`”, so the type of the member `a` in the constructed type above is “two-dimensional array of single-dimensional array of `int`”, or `int[,]`.

end example

Within instance function members, the type of `this` is the instance type (§14.3.2) of the containing declaration.

All members of a generic class can use type parameters from any enclosing class, either directly or as part of a constructed type. When a particular closed constructed type (§8.4.3) is used at run-time, each use of a type parameter is replaced with the type argument supplied to the constructed type.

Example:

```
C#
```

```

class C<V>
{
    public V f1;
    public C<V> f2 = null;

    public C(V x)
    {
        this.f1 = x;
        this.f2 = this;
    }
}

class Application
{
    static void Main()
    {
        C<int> x1 = new C<int>(1);
        Console.WriteLine(x1.f1);           // Prints 1

        C<double> x2 = new C<double>(3.1415);
        Console.WriteLine(x2.f1);         // Prints 3.1415
    }
}

```

end example

14.3.4 Inheritance

A class *inherits* the members of its direct base class. Inheritance means that a class implicitly contains all members of its direct base class, except for the instance constructors, finalizers, and static constructors of the base class. Some important aspects of inheritance are:

- Inheritance is transitive. If **C** is derived from **B**, and **B** is derived from **A**, then **C** inherits the members declared in **B** as well as the members declared in **A**.
- A derived class *extends* its direct base class. A derived class can add new members to those it inherits, but it cannot remove the definition of an inherited member.
- Instance constructors, finalizers, and static constructors are not inherited, but all other members are, regardless of their declared accessibility (§7.5). However, depending on their declared accessibility, inherited members might not be accessible in a derived class.
- A derived class can *hide* (§7.7.2.3) inherited members by declaring new members with the same name or signature. However, hiding an inherited member does not

remove that member—it merely makes that member inaccessible directly through the derived class.

- An instance of a class contains a set of all instance fields declared in the class and its base classes, and an implicit conversion (§10.2.8) exists from a derived class type to any of its base class types. Thus, a reference to an instance of some derived class can be treated as a reference to an instance of any of its base classes.
- A class can declare virtual methods, properties, indexers, and events, and derived classes can override the implementation of these function members. This enables classes to exhibit polymorphic behavior wherein the actions performed by a function member invocation vary depending on the run-time type of the instance through which that function member is invoked.

The inherited members of a constructed class type are the members of the immediate base class type (§14.2.4.2), which is found by substituting the type arguments of the constructed type for each occurrence of the corresponding type parameters in the *base_class_specification*. These members, in turn, are transformed by substituting, for each *type_parameter* in the member declaration, the corresponding *type_argument* of the *base_class_specification*.

Example:

```
C#  
  
class B<U>  
{  
    public U F(long index) {...}  
}  
  
class D<T> : B<T[]>  
{  
    public T G(string s) {...}  
}
```

In the code above, the constructed type `D<int>` has a non-inherited member `public int G(string s)` obtained by substituting the type argument `int` for the type parameter `T`. `D<int>` also has an inherited member from the class declaration `B`. This inherited member is determined by first determining the base class type `B<int[]>` of `D<int>` by substituting `int` for `T` in the base class specification `B<T[]>`. Then, as a type argument to `B`, `int[]` is substituted for `U` in `public U F(long index)`, yielding the inherited member `public int[] F(long index)`.

end example

14.3.5 The new modifier

A *class_member_declaration* is permitted to declare a member with the same name or signature as an inherited member. When this occurs, the derived class member is said to *hide* the base class member. See §7.7.2.3 for a precise specification of when a member hides an inherited member.

An inherited member *M* is considered to be *available* if *M* is accessible and there is no other inherited accessible member *N* that already hides *M*. Implicitly hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning unless the declaration of the derived class member includes a `new` modifier to explicitly indicate that the derived member is intended to hide the base member. If one or more parts of a partial declaration (§14.2.7) of a nested type include the `new` modifier, no warning is issued if the nested type hides an available inherited member.

If a `new` modifier is included in a declaration that doesn't hide an available inherited member, a warning to that effect is issued.

14.3.6 Access modifiers

A *class_member_declaration* can have any one of the permitted kinds of declared accessibility (§7.5.2): `public`, `protected internal`, `protected`, `private protected`, `internal`, or `private`. Except for the `protected internal` and `private protected` combinations, it is a compile-time error to specify more than one access modifier. When a *class_member_declaration* does not include any access modifiers, `private` is assumed.

14.3.7 Constituent types

Types that are used in the declaration of a member are called the *constituent types* of that member. Possible constituent types are the type of a constant, field, property, event, or indexer, the return type of a method or operator, and the parameter types of a method, indexer, operator, or instance constructor. The constituent types of a member shall be at least as accessible as that member itself (§7.5.5).

14.3.8 Static and instance members

Members of a class are either *static members* or *instance members*.

Note: Generally speaking, it is useful to think of static members as belonging to classes and instance members as belonging to objects (instances of classes). *end note*

When a field, method, property, event, operator, or constructor declaration includes a `static` modifier, it declares a static member. In addition, a constant or type declaration implicitly declares a static member. Static members have the following characteristics:

- When a static member `M` is referenced in a *member_access* (§11.7.6) of the form `E.M`, `E` shall denote a type that has a member `M`. It is a compile-time error for `E` to denote an instance.
- A static field in a non-generic class identifies exactly one storage location. No matter how many instances of a non-generic class are created, there is only ever one copy of a static field. Each distinct closed constructed type (§8.4.3) has its own set of static fields, regardless of the number of instances of the closed constructed type.
- A static function member (method, property, event, operator, or constructor) does not operate on a specific instance, and it is a compile-time error to refer to this in such a function member.

When a field, method, property, event, indexer, constructor, or finalizer declaration does not include a static modifier, it declares an instance member. (An instance member is sometimes called a non-static member.) Instance members have the following characteristics:

- When an instance member `M` is referenced in a *member_access* (§11.7.6) of the form `E.M`, `E` shall denote an instance of a type that has a member `M`. It is a binding-time error for `E` to denote a type.
- Every instance of a class contains a separate set of all instance fields of the class.
- An instance function member (method, property, indexer, instance constructor, or finalizer) operates on a given instance of the class, and this instance can be accessed as `this` (§11.7.12).

Example: The following example illustrates the rules for accessing static and instance members:

```
C#  
  
class Test  
{  
    int x;  
    static int y;  
    void F()  
    {  
        x = 1;           // Ok, same as this.x = 1  
        y = 1;           // Ok, same as Test.y = 1  
    }  
  
    static void G()  
}
```

```

    {
        x = 1;           // Error, cannot access this.x
        y = 1;           // Ok, same as Test.y = 1
    }

    static void Main()
    {
        Test t = new Test();
        t.x = 1;         // Ok
        t.y = 1;         // Error, cannot access static member through
instance
        Test.x = 1;     // Error, cannot access instance member through
type
        Test.y = 1;     // Ok
    }
}

```

The `F` method shows that in an instance function member, a *simple_name* (§11.7.4) can be used to access both instance members and static members. The `G` method shows that in a static function member, it is a compile-time error to access an instance member through a *simple_name*. The `Main` method shows that in a *member_access* (§11.7.6), instance members shall be accessed through instances, and static members shall be accessed through types.

end example

14.3.9 Nested types

14.3.9.1 General

A type declared within a class or struct is called a *nested type*. A type that is declared within a compilation unit or namespace is called a *non-nested type*.

Example: In the following example:

```

C#

class A
{
    class B
    {
        static void F()
        {
            Console.WriteLine("A.B.F");
        }
    }
}

```

class `B` is a nested type because it is declared within class `A`, and class `A` is a non-nested type because it is declared within a compilation unit.

end example

14.3.9.2 Fully qualified name

The fully qualified name (§7.8.3) for a nested type declaration is `S.N` where `S` is the fully qualified name of the type declaration in which type `N` is declared and `N` is the unqualified name (§7.8.2) of the nested type declaration (including any *generic_dimension_specifier* (§11.7.16)).

14.3.9.3 Declared accessibility

Non-nested types can have `public` or `internal` declared accessibility and have `internal` declared accessibility by default. Nested types can have these forms of declared accessibility too, plus one or more additional forms of declared accessibility, depending on whether the containing type is a class or struct:

- A nested type that is declared in a class can have any of the permitted kinds of declared accessibility and, like other class members, defaults to `private` declared accessibility.
- A nested type that is declared in a struct can have any of three forms of declared accessibility (`public`, `internal`, or `private`) and, like other struct members, defaults to `private` declared accessibility.

Example: The example

```
C#  
  
public class List  
{  
    // Private data structure  
    private class Node  
    {  
        public object Data;  
        public Node Next;  
  
        public Node(object data, Node next)  
        {  
            this.Data = data;  
            this.Next = next;  
        }  
    }  
}
```

```

private Node first = null;
private Node last = null;

// Public interface
public void AddToFront(object o) {...}
public void AddToBack(object o) {...}
public object RemoveFromFront() {...}
public object RemoveFromBack() {...}
public int Count { get {...} }
}

```

declares a private nested class `Node`.

end example

14.3.9.4 Hiding

A nested type may hide (§7.7.2.2) a base member. The `new` modifier (§14.3.5) is permitted on nested type declarations so that hiding can be expressed explicitly.

Example: The example

```

C#

class Base
{
    public static void M()
    {
        Console.WriteLine("Base.M");
    }
}

class Derived: Base
{
    public new class M
    {
        public static void F()
        {
            Console.WriteLine("Derived.M.F");
        }
    }
}

class Test
{
    static void Main()
    {
        Derived.M.F();
    }
}

```

shows a nested class `M` that hides the method `M` defined in `Base`.

end example

14.3.9.5 `this` access

A nested type and its containing type do not have a special relationship with regard to *this* access (§11.7.12). Specifically, `this` within a nested type cannot be used to refer to instance members of the containing type. In cases where a nested type needs access to the instance members of its containing type, access can be provided by providing the `this` for the instance of the containing type as a constructor argument for the nested type.

Example: The following example

```
C#  
  
class C  
{  
    int i = 123;  
    public void F()  
    {  
        Nested n = new Nested(this);  
        n.G();  
    }  
  
    public class Nested  
    {  
        C this_c;  
  
        public Nested(C c)  
        {  
            this_c = c;  
        }  
  
        public void G()  
        {  
            Console.WriteLine(this_c.i);  
        }  
    }  
}  
  
class Test  
{  
    static void Main()  
    {  
        C c = new C();  
        c.F();  
    }  
}
```

shows this technique. An instance of `C` creates an instance of `Nested`, and passes its own this to `Nested`'s constructor in order to provide subsequent access to `C`'s instance members.

end example

14.3.9.6 Access to private and protected members of the containing type

A nested type has access to all of the members that are accessible to its containing type, including members of the containing type that have `private` and `protected` declared accessibility.

Example: The example

```
C#  
  
class C  
{  
    private static void F() => Console.WriteLine("C.F");  
  
    public class Nested  
    {  
        public static void G() => F();  
    }  
}  
  
class Test  
{  
    static void Main() => C.Nested.G();  
}
```

shows a class `C` that contains a nested class `Nested`. Within `Nested`, the method `G` calls the static method `F` defined in `C`, and `F` has `private` declared accessibility.

end example

A nested type also may access protected members defined in a base type of its containing type.

Example: In the following code

```
C#
```

```

class Base
{
    protected void F() => Console.WriteLine("Base.F");
}

class Derived: Base
{
    public class Nested
    {
        public void G()
        {
            Derived d = new Derived();
            d.F(); // ok
        }
    }
}

class Test
{
    static void Main()
    {
        Derived.Nested n = new Derived.Nested();
        n.G();
    }
}

```

the nested class `Derived.Nested` accesses the protected method `F` defined in `Derived`'s base class, `Base`, by calling through an instance of `Derived`.

end example

14.3.9.7 Nested types in generic classes

A generic class declaration may contain nested type declarations. The type parameters of the enclosing class may be used within the nested types. A nested type declaration may contain additional type parameters that apply only to the nested type.

Every type declaration contained within a generic class declaration is implicitly a generic type declaration. When writing a reference to a type nested within a generic type, the containing constructed type, including its type arguments, shall be named. However, from within the outer class, the nested type may be used without qualification; the instance type of the outer class may be implicitly used when constructing the nested type.

Example: The following shows three different correct ways to refer to a constructed type created from `Inner`; the first two are equivalent:

C#

```
class Outer<T>
{
    class Inner<U>
    {
        public static void F(T t, U u) {...}
    }

    static void F(T t)
    {
        Outer<T>.Inner<string>.F(t, "abc"); // These two statements
have
        Inner<string>.F(t, "abc"); // the same effect
        Outer<int>.Inner<string>.F(3, "abc"); // This type is different
        Outer.Inner<string>.F(t, "abc"); // Error, Outer needs
type arg
    }
}
```

end example

Although it is bad programming style, a type parameter in a nested type can hide a member or type parameter declared in the outer type.

Example:

C#

```
class Outer<T>
{
    class Inner<T> // Valid, hides
Outer's T
    {
        public T t; // Refers to Inner's
T
    }
}
```

end example

14.3.10 Reserved member names

14.3.10.1 General

To facilitate the underlying C# run-time implementation, for each source member declaration that is a property, event, or indexer, the implementation shall reserve two

method signatures based on the kind of the member declaration, its name, and its type (§14.3.10.2, §14.3.10.3, §14.3.10.4). It is a compile-time error for a program to declare a member whose signature matches a signature reserved by a member declared in the same scope, even if the underlying run-time implementation does not make use of these reservations.

The reserved names do not introduce declarations, thus they do not participate in member lookup. However, a declaration's associated reserved method signatures do participate in inheritance (§14.3.4), and can be hidden with the `new` modifier (§14.3.5).

Note: The reservation of these names serves three purposes:

1. To allow the underlying implementation to use an ordinary identifier as a method name for get or set access to the C# language feature.
2. To allow other languages to interoperate using an ordinary identifier as a method name for get or set access to the C# language feature.
3. To help ensure that the source accepted by one conforming compiler is accepted by another, by making the specifics of reserved member names consistent across all C# implementations.

end note

The declaration of a finalizer (§14.13) also causes a signature to be reserved (§14.3.10.5).

14.3.10.2 Member names reserved for properties

For a property `P` (§14.7) of type `T`, the following signatures are reserved:

C#

```
T get_P();  
void set_P(T value);
```

Both signatures are reserved, even if the property is read-only or write-only.

Example: In the following code

C#

```
class A  
{  
    public int P  
    {  
        get => 123;  
    }  
}
```

```

    }
}

class B : A
{
    public new int get_P() => 456;

    public new void set_P(int value)
    {
    }
}

class Test
{
    static void Main()
    {
        B b = new B();
        A a = b;
        Console.WriteLine(a.P);
        Console.WriteLine(b.P);
        Console.WriteLine(b.get_P());
    }
}

```

A class `A` defines a read-only property `P`, thus reserving signatures for `get_P` and `set_P` methods. A class `B` derives from `A` and hides both of these reserved signatures. The example produces the output:

Console

```

123
123
456

```

end example

14.3.10.3 Member names reserved for events

For an event `E` (§14.8) of delegate type `T`, the following signatures are reserved:

C#

```

void add_E(T handler);
void remove_E(T handler);

```

14.3.10.4 Member names reserved for indexers

For an indexer (§14.9) of type `T` with parameter-list `L`, the following signatures are reserved:

C#

```
T get_Item(L);  
void set_Item(L, T value);
```

Both signatures are reserved, even if the indexer is read-only or write-only.

Furthermore the member name `Item` is reserved.

14.3.10.5 Member names reserved for finalizers

For a class containing a finalizer (§14.13), the following signature is reserved:

C#

```
void Finalize();
```

14.4 Constants

A *constant* is a class member that represents a constant value: a value that can be computed at compile-time. A *constant_declaration* introduces one or more constants of a given type.

ANTLR

```
constant_declaration  
    : attributes? constant_modifier* 'const' type constant_declarators ';' ;  
;  
  
constant_modifier  
    : 'new'  
    | 'public'  
    | 'protected'  
    | 'internal'  
    | 'private'  
    ;
```

A *constant_declaration* may include a set of *attributes* (§21), a `new` modifier (§14.3.5), and any one of the permitted kinds of declared accessibility (§14.3.6). The attributes and modifiers apply to all of the members declared by the *constant_declaration*. Even though constants are considered static members, a *constant_declaration* neither requires nor

allows a `static` modifier. It is an error for the same modifier to appear multiple times in a constant declaration.

The *type* of a *constant_declaration* specifies the type of the members introduced by the declaration. The type is followed by a list of *constant_declarators* (§12.6.3), each of which introduces a new member. A *constant_declarator* consists of an *identifier* that names the member, followed by an "=" token, followed by a *constant_expression* (§11.21) that gives the value of the member.

The *type* specified in a constant declaration shall be `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `string`, an *enum_type*, or a *reference_type*. Each *constant_expression* shall yield a value of the target type or of a type that can be converted to the target type by an implicit conversion (§10.2).

The *type* of a constant shall be at least as accessible as the constant itself (§7.5.5).

The value of a constant is obtained in an expression using a *simple_name* (§11.7.4) or a *member_access* (§11.7.6).

A constant can itself participate in a *constant_expression*. Thus, a constant may be used in any construct that requires a *constant_expression*.

Note: Examples of such constructs include `case` labels, `goto case` statements, `enum` member declarations, attributes, and other constant declarations. *end note*

Note: As described in §11.21, a *constant_expression* is an expression that can be fully evaluated at compile-time. Since the only way to create a non-null value of a *reference_type* other than `string` is to apply the `new` operator, and since the `new` operator is not permitted in a *constant_expression*, the only possible value for constants of *reference_types* other than `string` is `null`. *end note*

When a symbolic name for a constant value is desired, but when the type of that value is not permitted in a constant declaration, or when the value cannot be computed at compile-time by a *constant_expression*, a readonly field (§14.5.3) may be used instead.

Note: The versioning semantics of `const` and `readonly` differ (§14.5.3.3). *end note*

A constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same attributes, modifiers, and type.

Example:

C#

```
class A
{
    public const double X = 1.0, Y = 2.0, Z = 3.0;
}
```

is equivalent to

C#

```
class A
{
    public const double X = 1.0;
    public const double Y = 2.0;
    public const double Z = 3.0;
}
```

end example

Constants are permitted to depend on other constants within the same program as long as the dependencies are not of a circular nature. The compiler automatically arranges to evaluate the constant declarations in the appropriate order.

Example: In the following code

C#

```
class A
{
    public const int X = B.Z + 1;
    public const int Y = 10;
}

class B
{
    public const int Z = A.Y + 1;
}
```

the compiler first evaluates `A.Y`, then evaluates `B.Z`, and finally evaluates `A.X`, producing the values `10`, `11`, and `12`.

end example

Constant declarations may depend on constants from other programs, but such dependencies are only possible in one direction.

Example: Referring to the example above, if `A` and `B` were declared in separate programs, it would be possible for `A.X` to depend on `B.Z`, but `B.Z` could then not simultaneously depend on `A.Y`. *end example*

14.5 Fields

14.5.1 General

A *field* is a member that represents a variable associated with an object or class. A *field_declaration* introduces one or more fields of a given type.

ANTLR

```
field_declaration
    : attributes? field_modifier* type variable_declarators ';'
    ;

field_modifier
    : 'new'
    | 'public'
    | 'protected'
    | 'internal'
    | 'private'
    | 'static'
    | 'readonly'
    | 'volatile'
    | unsafe_modifier // unsafe code support
    ;

variable_declarators
    : variable_declarator (',' variable_declarator)*
    ;

variable_declarator
    : identifier ('=' variable_initializer)?
    ;
```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

A *field_declaration* may include a set of *attributes* (§21), a `new` modifier (§14.3.5), a valid combination of the four access modifiers (§14.3.6), and a `static` modifier (§14.5.2). In addition, a *field_declaration* may include a `readonly` modifier (§14.5.3) or a `volatile` modifier (§14.5.4), but not both. The attributes and modifiers apply to all of the members declared by the *field_declaration*. It is an error for the same modifier to appear multiple times in a *field_declaration*.

The *type* of a *field_declaration* specifies the type of the members introduced by the declaration. The type is followed by a list of *variable_declarators*, each of which introduces a new member. A *variable_declarator* consists of an *identifier* that names that member, optionally followed by an "=" token and a *variable_initializer* (§14.5.6) that gives the initial value of that member.

The *type* of a field shall be at least as accessible as the field itself (§7.5.5).

The value of a field is obtained in an expression using a *simple_name* (§11.7.4), a *member_access* (§11.7.6) or a *base_access* (§11.7.13). The value of a non-readonly field is modified using an *assignment* (§11.19). The value of a non-readonly field can be both obtained and modified using postfix increment and decrement operators (§11.7.14) and prefix increment and decrement operators (§11.8.6).

A field declaration that declares multiple fields is equivalent to multiple declarations of single fields with the same attributes, modifiers, and type.

Example:

```
C#  
  
class A  
{  
    public static int X = 1, Y, Z = 100;  
}
```

is equivalent to

```
C#  
  
class A  
{  
    public static int X = 1;  
    public static int Y;  
    public static int Z = 100;  
}
```

end example

14.5.2 Static and instance fields

When a field declaration includes a `static` modifier, the fields introduced by the declaration are *static fields*. When no `static` modifier is present, the fields introduced by the declaration are *instance fields*. Static fields and instance fields are two of the

several kinds of variables (§9) supported by C#, and at times they are referred to as *static variables* and *instance variables*, respectively.

As explained in §14.3.8, each instance of a class contains a complete set of the instance fields of the class, while there is only one set of static fields for each non-generic class or closed constructed type, regardless of the number of instances of the class or closed constructed type.

14.5.3 Readonly fields

14.5.3.1 General

When a *field_declaration* includes a `readonly` modifier, the fields introduced by the declaration are *readonly fields*. Direct assignments to readonly fields can only occur as part of that declaration or in an instance constructor or static constructor in the same class. (A readonly field can be assigned to multiple times in these contexts.) Specifically, direct assignments to a readonly field are permitted only in the following contexts:

- In the *variable_declarator* that introduces the field (by including a *variable_initializer* in the declaration).
- For an instance field, in the instance constructors of the class that contains the field declaration; for a static field, in the static constructor of the class that contains the field declaration. These are also the only contexts in which it is valid to pass a readonly field as an `out` or `ref` parameter.

Attempting to assign to a readonly field or pass it as an `out` or `ref` parameter in any other context is a compile-time error.

14.5.3.2 Using static readonly fields for constants

A static readonly field is useful when a symbolic name for a constant value is desired, but when the type of the value is not permitted in a `const` declaration, or when the value cannot be computed at compile-time.

Example: In the following code

```
C#  
  
public class Color  
{  
    public static readonly Color Black = new Color(0, 0, 0);  
    public static readonly Color White = new Color(255, 255, 255);  
    public static readonly Color Red = new Color(255, 0, 0);  
}
```

```

public static readonly Color Green = new Color(0, 255, 0);
public static readonly Color Blue = new Color(0, 0, 255);

private byte red, green, blue;

public Color(byte r, byte g, byte b)
{
    red = r;
    green = g;
    blue = b;
}
}

```

the `Black`, `White`, `Red`, `Green`, and `Blue` members cannot be declared as `const` members because their values cannot be computed at compile-time. However, declaring them `static readonly` instead has much the same effect.

end example

14.5.3.3 Versioning of constants and static readonly fields

Constants and readonly fields have different binary versioning semantics. When an expression references a constant, the value of the constant is obtained at compile-time, but when an expression references a readonly field, the value of the field is not obtained until run-time.

Example: Consider an application that consists of two separate programs:

```

C#

namespace Program1
{
    public class Utils
    {
        public static readonly int x = 1;
    }
}

```

and

```

C#

namespace Program2
{
    class Test
    {
        static void Main()
        {

```

```
        Console.WriteLine(Program1.Utils.X);
    }
}
}
```

The `Program1` and `Program2` namespaces denote two programs that are compiled separately. Because `Program1.Utils.X` is declared as a `static readonly` field, the value output by the `Console.WriteLine` statement is not known at compile-time, but rather is obtained at run-time. Thus, if the value of `x` is changed and `Program1` is recompiled, the `Console.WriteLine` statement will output the new value even if `Program2` isn't recompiled. However, had `x` been a constant, the value of `x` would have been obtained at the time `Program2` was compiled, and would remain unaffected by changes in `Program1` until `Program2` is recompiled.

end example

14.5.4 Volatile fields

When a *field_declaration* includes a `volatile` modifier, the fields introduced by that declaration are **volatile fields**. For non-volatile fields, optimization techniques that reorder instructions can lead to unexpected and unpredictable results in multi-threaded programs that access fields without synchronization such as that provided by the *lock_statement* (§12.13). These optimizations can be performed by the compiler, by the run-time system, or by hardware. For volatile fields, such reordering optimizations are restricted:

- A read of a volatile field is called a **volatile read**. A volatile read has “acquire semantics”; that is, it is guaranteed to occur prior to any references to memory that occur after it in the instruction sequence.
- A write of a volatile field is called a **volatile write**. A volatile write has “release semantics”; that is, it is guaranteed to happen after any memory references prior to the write instruction in the instruction sequence.

These restrictions ensure that all threads will observe volatile writes performed by any other thread in the order in which they were performed. A conforming implementation is not required to provide a single total ordering of volatile writes as seen from all threads of execution. The type of a volatile field shall be one of the following:

- A *reference_type*.
- A *type_parameter* that is known to be a reference type (§14.2.5).
- The type `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `char`, `float`, `bool`, `System.IntPtr`, or `System.UIntPtr`.

- An `enum_type` having an `enum_base` type of `byte`, `sbyte`, `short`, `ushort`, `int`, or `uint`.

Example: The example

```
C#  
  
class Test  
{  
    public static int result;  
    public static volatile bool finished;  
  
    static void Thread2()  
    {  
        result = 143;  
        finished = true;  
    }  
  
    static void Main()  
    {  
        finished = false;  
  
        // Run Thread2() in a new thread  
        new Thread(new ThreadStart(Thread2)).Start();  
  
        // Wait for Thread2() to signal that it has a result  
        // by setting finished to true.  
        for (;;)   
        {  
            if (finished)  
            {  
                Console.WriteLine($"result = {result}");  
                return;  
            }  
        }  
    }  
}
```

produces the output:

```
Console
```

```
result = 143
```

In this example, the method `Main` starts a new thread that runs the method `Thread2`. This method stores a value into a non-volatile field called `result`, then stores `true` in the volatile field `finished`. The main thread waits for the field `finished` to be set to `true`, then reads the field `result`. Since `finished` has been

declared `volatile`, the main thread shall read the value `143` from the field `result`. If the field `finished` had not been declared `volatile`, then it would be permissible for the store to `result` to be visible to the main thread *after* the store to `finished`, and hence for the main thread to read the value `0` from the field `result`. Declaring `finished` as a `volatile` field prevents any such inconsistency.

end example

14.5.5 Field initialization

The initial value of a field, whether it be a static field or an instance field, is the default value (§9.3) of the field's type. It is not possible to observe the value of a field before this default initialization has occurred, and a field is thus never "uninitialized".

Example: The example

C#

```
class Test
{
    static bool b;
    int i;

    static void Main()
    {
        Test t = new Test();
        Console.WriteLine($"b = {b}, i = {t.i}");
    }
}
```

produces the output

Console

```
b = False, i = 0
```

because `b` and `i` are both automatically initialized to default values.

end example

14.5.6 Variable initializers

14.5.6.1 General

Field declarations may include *variable_initializers*. For static fields, variable initializers correspond to assignment statements that are executed during class initialization. For instance fields, variable initializers correspond to assignment statements that are executed when an instance of the class is created.

Example: The example

```
C#  
  
class Test  
{  
    static double x = Math.Sqrt(2.0);  
    int i = 100;  
    string s = "Hello";  
  
    static void Main()  
    {  
        Test a = new Test();  
        Console.WriteLine($"x = {x}, i = {a.i}, s = {a.s}");  
    }  
}
```

produces the output

```
Console  
  
x = 1.4142135623730951, i = 100, s = Hello
```

because an assignment to `x` occurs when static field initializers execute and assignments to `i` and `s` occur when the instance field initializers execute.

end example

The default value initialization described in §14.5.5 occurs for all fields, including fields that have variable initializers. Thus, when a class is initialized, all static fields in that class are first initialized to their default values, and then the static field initializers are executed in textual order. Likewise, when an instance of a class is created, all instance fields in that instance are first initialized to their default values, and then the instance field initializers are executed in textual order. When there are field declarations in multiple partial type declarations for the same type, the order of the parts is unspecified. However, within each part the field initializers are executed in order.

It is possible for static fields with variable initializers to be observed in their default value state.

Example: However, this is strongly discouraged as a matter of style. The example

```
C#  
  
class Test  
{  
    static int a = b + 1;  
    static int b = a + 1;  
  
    static void Main()  
    {  
        Console.WriteLine($"a = {a}, b = {b}");  
    }  
}
```

exhibits this behavior. Despite the circular definitions of `a` and `b`, the program is valid. It results in the output

```
Console  
  
a = 1, b = 2
```

because the static fields `a` and `b` are initialized to `0` (the default value for `int`) before their initializers are executed. When the initializer for `a` runs, the value of `b` is zero, and so `a` is initialized to `1`. When the initializer for `b` runs, the value of `a` is already `1`, and so `b` is initialized to `2`.

end example

14.5.6.2 Static field initialization

The static field variable initializers of a class correspond to a sequence of assignments that are executed in the textual order in which they appear in the class declaration (§14.5.6.1). Within a partial class, the meaning of “textual order” is specified by §14.5.6.1. If a static constructor (§14.12) exists in the class, execution of the static field initializers occurs immediately prior to executing that static constructor. Otherwise, the static field initializers are executed at an implementation-dependent time prior to the first use of a static field of that class.

Example: The example

```
C#  
  
class Test  
{
```

```

static void Main()
{
    Console.WriteLine($"{B.Y} {A.X}");
}

public static int F(string s)
{
    Console.WriteLine(s);
    return 1;
}
}

class A
{
    public static int X = Test.F("Init A");
}

class B
{
    public static int Y = Test.F("Init B");
}

```

might produce either the output:

Console

```

Init A
Init B
1 1

```

or the output:

Console

```

Init B
Init A
1 1

```

because the execution of `X`'s initializer and `Y`'s initializer could occur in either order; they are only constrained to occur before the references to those fields. However, in the example:

C#

```

class Test
{
    static void Main()
    {
        Console.WriteLine($"{B.Y} {A.X}");
    }
}

```

```

    public static int F(string s)
    {
        Console.WriteLine(s);
        return 1;
    }
}

class A
{
    static A() {}
    public static int X = Test.F("Init A");
}

class B
{
    static B() {}
    public static int Y = Test.F("Init B");
}

```

the output shall be:

Console

```

Init B
Init A
1 1

```

because the rules for when static constructors execute (as defined in §14.12) provide that **B**'s static constructor (and hence **B**'s static field initializers) shall run before **A**'s static constructor and field initializers.

end example

14.5.6.3 Instance field initialization

The instance field variable initializers of a class correspond to a sequence of assignments that are executed immediately upon entry to any one of the instance constructors (§14.11.3) of that class. Within a partial class, the meaning of “textual order” is specified by §14.5.6.1. The variable initializers are executed in the textual order in which they appear in the class declaration (§14.5.6.1). The class instance creation and initialization process is described further in §14.11.

A variable initializer for an instance field cannot reference the instance being created. Thus, it is a compile-time error to reference `this` in a variable initializer, as it is a compile-time error for a variable initializer to reference any instance member through a *simple_name*.

Example: In the following code

```
C#  
  
class A  
{  
    int x = 1;  
    int y = x + 1;    // Error, reference to instance member of this  
}
```

the variable initializer for `y` results in a compile-time error because it references a member of the instance being created.

end example

14.6 Methods

14.6.1 General

A **method** is a member that implements a computation or action that can be performed by an object or class. Methods are declared using *method_declarations*:

ANTLR

```
method_declaration  
    : method_header method_body  
    ;  
  
method_header  
    : attributes? method_modifier* 'partial'? return_type member_name  
      type_parameter_list? '(' formal_parameter_list? ')'  
      type_parameter_constraints_clause*  
    ;  
  
method_modifier  
    : 'new'  
    | 'public'  
    | 'protected'  
    | 'internal'  
    | 'private'  
    | 'static'  
    | 'virtual'  
    | 'sealed'  
    | 'override'  
    | 'abstract'  
    | 'extern'  
    | 'async'  
    | unsafe_modifier    // unsafe code support
```

```

;

return_type
: type
| 'void'
;

member_name
: identifier
| interface_type '.' identifier
;

method_body
: block
| '=>' null_conditional_invocation_expression ';'
| '=>' expression ';'
| ';'
;

```

Grammar notes:

- *unsafe_modifier* (§22.2) is only available in unsafe code (§22).
- when recognising a *method_body* if both the *null_conditional_invocation_expression* and *expression* alternatives are applicable then the former shall be chosen.

Note: The overlapping of, and priority between, alternatives here is solely for descriptive convenience; the grammar rules could be elaborated to remove the overlap. ANTLR, and other grammar systems, adopt the same convenience and so *method_body* has the specified semantics automatically.

A *method_declaration* may include a set of *attributes* (§21) and one of the permitted kinds of declared accessibility (§14.3.6), the `new` (§14.3.5), `static` (§14.6.3), `virtual` (§14.6.4), `override` (§14.6.5), `sealed` (§14.6.6), `abstract` (§14.6.7), `extern` (§14.6.8) and `async` (§14.15) modifiers.

A declaration has a valid combination of modifiers if all of the following are true:

- The declaration includes a valid combination of access modifiers (§14.3.6).
- The declaration does not include the same modifier multiple times.
- The declaration includes at most one of the following modifiers: `static`, `virtual`, and `override`.
- The declaration includes at most one of the following modifiers: `new` and `override`.
- If the declaration includes the `abstract` modifier, then the declaration does not include any of the following modifiers: `static`, `virtual`, `sealed`, or `extern`.

- If the declaration includes the `private` modifier, then the declaration does not include any of the following modifiers: `virtual`, `override`, or `abstract`.
- If the declaration includes the `sealed` modifier, then the declaration also includes the `override` modifier.
- If the declaration includes the `partial` modifier, then it does not include any of the following modifiers: `new`, `public`, `protected`, `internal`, `private`, `virtual`, `sealed`, `override`, `abstract`, or `extern`.

The *return_type* of a method declaration specifies the type of the value computed and returned by the method. The *return_type* is `void` if the method does not return a value. If the declaration includes the `partial` modifier, then the return type shall be `void` (§14.6.9). If the declaration includes the `async` modifier then the return type shall be `void` or a *task type* (§14.15.1).

A generic method is a method whose declaration includes a *type_parameter_list*. This specifies the type parameters for the method. The optional *type_parameter_constraints_clauses* specify the constraints for the type parameters. A *method_declaration* shall not have *type_parameter_constraints_clauses* unless it also has a *type_parameter_list*. A *method_declaration* for an explicit interface member implementation shall not have any *type_parameter_constraints_clauses*. A generic *method_declaration* for an explicit interface member implementation inherits any constraints from the constraints on the interface method. Similarly, a method declaration with the `override` modifier shall not have any *type_parameter_constraints_clauses* and the constraints of the method's type parameters are inherited from the virtual method being overridden. The *member_name* specifies the name of the method. Unless the method is an explicit interface member implementation (§17.6.2), the *member_name* is simply an *identifier*. For an explicit interface member implementation, the *member_name* consists of an *interface_type* followed by a "." and an *identifier*. In this case, the declaration shall include no modifiers other than (possibly) `extern` or `async`.

The optional *formal_parameter_list* specifies the parameters of the method (§14.6.2).

The *return_type* and each of the types referenced in the *formal_parameter_list* of a method shall be at least as accessible as the method itself (§7.5.5).

The *method_body* is either a semicolon, a **block body** or an **expression body**. A block body consists of a *block*, which specifies the statements to execute when the method is invoked. An expression body consists of `=>`, followed by a *null_conditional_invocation_expression* or *expression*, followed by a semicolon, and denotes a single expression to perform when the method is invoked.

For abstract and extern methods, the *method_body* consists simply of a semicolon. For partial methods the *method_body* may consist of either a semicolon, a block body or an expression body. For all other methods, the *method_body* is either a block body or an expression body.

If the *method_body* consists of a semicolon, the declaration shall not include the `async` modifier.

The name, the number of type parameters, and the formal parameter list of a method define the signature (§7.6) of the method. Specifically, the signature of a method consists of its name, the number of its type parameters, and the number, *parameter_mode_modifiers* (§14.6.2.1), and types of its formal parameters. The return type is not part of a method's signature, nor are the names of the formal parameters, the names of the type parameters, or the constraints. When a formal parameter type references a type parameter of the method, the ordinal position of the type parameter (not the name of the type parameter) is used for type equivalence.

The name of a method shall differ from the names of all other non-methods declared in the same class. In addition, the signature of a method shall differ from the signatures of all other methods declared in the same class, and two methods declared in the same class may not have signatures that differ solely by `ref` and `out`.

The method's *type_parameters* are in scope throughout the *method_declaration*, and can be used to form types throughout that scope in *return_type*, *method_body*, and *type_parameter_constraints_clauses* but not in *attributes*.

All formal parameters and type parameters shall have different names.

14.6.2 Method parameters

14.6.2.1 General

The parameters of a method, if any, are declared by the method's *formal_parameter_list*.

ANTLR

```
formal_parameter_list
    : fixed_parameters
    | fixed_parameters ',' parameter_array
    | parameter_array
    ;

fixed_parameters
    : fixed_parameter (',' fixed_parameter)*
    ;
```

```

fixed_parameter
  : attributes? parameter_modifier? type identifier default_argument?
  ;

default_argument
  : '=' expression
  ;

parameter_modifier
  : parameter_mode_modifier
  | 'this'
  ;

parameter_mode_modifier
  : 'ref'
  | 'out'
  ;

parameter_array
  : attributes? 'params' array_type identifier
  ;

```

The formal parameter list consists of one or more comma-separated parameters of which only the last may be a *parameter_array*.

A *fixed_parameter* consists of an optional set of *attributes* (§21); an optional `ref`, `out`, or `this` modifier; a *type*; an *identifier*; and an optional *default_argument*. Each *fixed_parameter* declares a parameter of the given type with the given name. The `this` modifier designates the method as an extension method and is only allowed on the first parameter of a static method in a non-generic, non-nested static class. Extension methods are further described in §14.6.10. A *fixed_parameter* with a *default_argument* is known as an **optional parameter**, whereas a *fixed_parameter* without a *default_argument* is a **required parameter**. A required parameter may not appear after an optional parameter in a *formal_parameter_list*.

A parameter with a `ref`, `out` or `this` modifier cannot have a *default_argument*. The *expression* in a *default_argument* shall be one of the following:

- a *constant_expression*
- an expression of the form `new S()` where `S` is a value type
- an expression of the form `default(S)` where `S` is a value type

The *expression* shall be implicitly convertible by an identity or nullable conversion to the type of the parameter.

If optional parameters occur in an implementing partial method declaration (§14.6.9), an explicit interface member implementation (§17.6.2), a single-parameter indexer declaration (§14.9), or in an operator declaration (§14.10.1) the compiler should give a warning, since these members can never be invoked in a way that permits arguments to be omitted.

A *parameter_array* consists of an optional set of *attributes* (§21), a `params` modifier, an *array_type*, and an *identifier*. A parameter array declares a single parameter of the given array type with the given name. The *array_type* of a parameter array shall be a single-dimensional array type (§16.2). In a method invocation, a parameter array permits either a single argument of the given array type to be specified, or it permits zero or more arguments of the array element type to be specified. Parameter arrays are described further in §14.6.2.5.

A *parameter_array* may occur after an optional parameter, but cannot have a default value – the omission of arguments for a *parameter_array* would instead result in the creation of an empty array.

Example: The following illustrates different kinds of parameters:

```
C#  
  
void M<T>(  
    ref int i,  
    decimal d,  
    bool b = false,  
    bool? n = false,  
    string s = "Hello",  
    object o = null,  
    T t = default(T),  
    params int[] a  
) { }
```

In the *formal_parameter_list* for `M`, `i` is a required `ref` parameter, `d` is a required value parameter, `b`, `s`, `o` and `t` are optional value parameters and `a` is a parameter array.

end example

A method declaration creates a separate declaration space (§7.3) for parameters and type parameters. Names are introduced into this declaration space by the type parameter list and the formal parameter list of the method. The body of the method, if any, is considered to be nested within this declaration space. It is an error for two members of a method declaration space to have the same name. It is an error for the

method declaration space and the local variable declaration space of a nested declaration space to contain elements with the same name.

A method invocation (§11.7.8.2) creates a copy, specific to that invocation, of the formal parameters and local variables of the method, and the argument list of the invocation assigns values or variable references to the newly created formal parameters. Within the *block* of a method, formal parameters can be referenced by their identifiers in *simple_name* expressions (§11.7.4).

There are four kinds of formal parameters:

- Value parameters, which are declared without any modifiers.
- Reference parameters, which are declared with the `ref` modifier.
- Output parameters, which are declared with the `out` modifier.
- Parameter arrays, which are declared with the `params` modifier.

Note: As described in §7.6, the `ref` and `out` modifiers are part of a method's signature, but the `params` modifier is not.

14.6.2.2 Value parameters

A parameter declared with no modifiers is a value parameter. A value parameter corresponds to a local variable that gets its initial value from the corresponding argument supplied in the method invocation.

When a formal parameter is a value parameter, the corresponding argument in a method invocation shall be an expression that is implicitly convertible (§10.2) to the formal parameter type.

A method is permitted to assign new values to a value parameter. Such assignments only affect the local storage location represented by the value parameter—they have no effect on the actual argument given in the method invocation.

14.6.2.3 Reference parameters

A parameter declared with a `ref` modifier is a reference parameter. Unlike a value parameter, a reference parameter does not create a new storage location. Instead, a reference parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is a reference parameter, the corresponding argument in a method invocation shall consist of the keyword `ref` followed by a *variable_reference*

(§9.5) of the same type as the formal parameter. A variable shall be definitely assigned before it can be passed as a reference parameter.

Within a method, a reference parameter is always considered definitely assigned.

A method declared as an iterator (§14.14) may not have reference parameters.

Example: The example

```
C#  
  
class Test  
{  
    static void Swap(ref int x, ref int y)  
    {  
        int temp = x;  
        x = y;  
        y = temp;  
    }  
  
    static void Main()  
    {  
        int i = 1, j = 2;  
        Swap(ref i, ref j);  
        Console.WriteLine($"i = {i}, j = {j}");  
    }  
}
```

produces the output

```
Console  
  
i = 2, j = 1
```

For the invocation of `Swap` in `Main`, `x` represents `i` and `y` represents `j`. Thus, the invocation has the effect of swapping the values of `i` and `j`.

end example

In a method that takes reference parameters, it is possible for multiple names to represent the same storage location.

Example: In the following code

```
C#  
  
class A  
{
```

```

string s;
void F(ref string a, ref string b)
{
    s = "One";
    a = "Two";
    b = "Three";
}

void G()
{
    F(ref s, ref s);
}
}

```

the invocation of `F` in `G` passes a reference to `s` for both `a` and `b`. Thus, for that invocation, the names `s`, `a`, and `b` all refer to the same storage location, and the three assignments all modify the instance field `s`.

end example

14.6.2.4 Output parameters

A parameter declared with an `out` modifier is an output parameter. Similar to a reference parameter, an output parameter does not create a new storage location. Instead, an output parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is an output parameter, the corresponding argument in a method invocation shall consist of the keyword `out` followed by a *variable_reference* (§9.5) of the same type as the formal parameter. A variable need not be definitely assigned before it can be passed as an output parameter, but following an invocation where a variable was passed as an output parameter, the variable is considered definitely assigned.

Within a method, just like a local variable, an output parameter is initially considered unassigned and shall be definitely assigned before its value is used.

Every output parameter of a method shall be definitely assigned before the method returns.

A method declared as a partial method (§14.6.9) or an iterator (§14.14) may not have output parameters.

Output parameters are typically used in methods that produce multiple return values.

Example:

C#

```
class Test
{
    static void SplitPath(string path, out string dir, out string name)
    {
        int i = path.Length;
        while (i > 0)
        {
            char ch = path[i - 1];
            if (ch == '\\\' || ch == '/' || ch == ':')
            {
                break;
            }
            i--;
        }
        dir = path.Substring(0, i);
        name = path.Substring(i);
    }

    static void Main()
    {
        string dir, name;
        SplitPath(@"c:\Windows\System\hello.txt", out dir, out name);
        Console.WriteLine(dir);
        Console.WriteLine(name);
    }
}
```

The example produces the output:

Console

```
c:\Windows\System\
hello.txt
```

Note that the `dir` and `name` variables can be unassigned before they are passed to `SplitPath`, and that they are considered definitely assigned following the call.

end example

14.6.2.5 Parameter arrays

A parameter declared with a `params` modifier is a parameter array. If a formal parameter list includes a parameter array, it shall be the last parameter in the list and it shall be of a single-dimensional array type.

Example: The types `string[]` and `string[][]` can be used as the type of a parameter array, but the type `string[,]` can not. *end example*

It is not possible to combine the `params` modifier with the modifiers `ref` and `out`.

A parameter array permits arguments to be specified in one of two ways in a method invocation:

- The argument given for a parameter array can be a single expression that is implicitly convertible (§10.2) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.
- Alternatively, the invocation can specify zero or more arguments for the parameter array, where each argument is an expression that is implicitly convertible (§10.2) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

Except for allowing a variable number of arguments in an invocation, a parameter array is precisely equivalent to a value parameter (§14.6.2.2) of the same type.

Example: The example

```
C#  
  
class Test  
{  
    static void F(params int[] args)  
    {  
        Console.WriteLine($"Array contains {args.Length} elements:");  
        foreach (int i in args)  
        {  
            Console.WriteLine($" {i}");  
        }  
        Console.WriteLine();  
    }  
  
    static void Main()  
    {  
        int[] arr = {1, 2, 3};  
        F(arr);  
        F(10, 20, 30, 40);  
        F();  
    }  
}
```

produces the output

Console

```
Array contains 3 elements: 1 2 3  
Array contains 4 elements: 10 20 30 40  
Array contains 0 elements:
```

The first invocation of `F` simply passes the array `arr` as a value parameter. The second invocation of `F` automatically creates a four-element `int[]` with the given element values and passes that array instance as a value parameter. Likewise, the third invocation of `F` creates a zero-element `int[]` and passes that instance as a value parameter. The second and third invocations are precisely equivalent to writing:

C#

```
F(new int[] {10, 20, 30, 40});  
F(new int[] {});
```

end example

When performing overload resolution, a method with a parameter array might be applicable, either in its normal form or in its expanded form (§11.6.4.2). The expanded form of a method is available only if the normal form of the method is not applicable and only if an applicable method with the same signature as the expanded form is not already declared in the same type.

Example: The example

C#

```
class Test  
{  
    static void F(params object[] a) =>  
        Console.WriteLine("F(object[])");  
  
    static void F() =>  
        Console.WriteLine("F()");  
  
    static void F(object a0, object a1) =>  
        Console.WriteLine("F(object,object)");  
  
    static void Main()  
    {  
        F();  
        F(1);  
        F(1, 2);  
    }  
}
```

```
        F(1, 2, 3);
        F(1, 2, 3, 4);
    }
}
```

produces the output

Console

```
F()
F(object[])
F(object,object)
F(object[])
F(object[])
```

In the example, two of the possible expanded forms of the method with a parameter array are already included in the class as regular methods. These expanded forms are therefore not considered when performing overload resolution, and the first and third method invocations thus select the regular methods. When a class declares a method with a parameter array, it is not uncommon to also include some of the expanded forms as regular methods. By doing so, it is possible to avoid the allocation of an array instance that occurs when an expanded form of a method with a parameter array is invoked.

end example

An array is a reference type, so the value passed for a parameter array can be `null`.

Example: The example:

```
C#

class Test
{
    static void F(params string[] array) =>
        Console.WriteLine(array == null);

    static void Main()
    {
        F(null);
        F((string) null);
    }
}
```

produces the output:

Console

True
False

The second invocation produces `False` as it is equivalent to `F(new string[] { null })` and passes an array containing a single null reference.

end example

When the type of a parameter array is `object[]`, a potential ambiguity arises between the normal form of the method and the expanded form for a single `object` parameter. The reason for the ambiguity is that an `object[]` is itself implicitly convertible to type `object`. The ambiguity presents no problem, however, since it can be resolved by inserting a cast if needed.

Example: The example

C#

```
class Test
{
    static void F(params object[] args)
    {
        foreach (object o in args)
        {
            Console.Write(o.GetType().FullName);
            Console.Write(" ");
        }
        Console.WriteLine();
    }

    static void Main()
    {
        object[] a = {1, "Hello", 123.456};
        object o = a;
        F(a);
        F((object)a);
        F(o);
        F((object[])o);
    }
}
```

produces the output

Console

```
System.Int32 System.String System.Double  
System.Object[]  
System.Object[]  
System.Int32 System.String System.Double
```

In the first and last invocations of `F`, the normal form of `F` is applicable because an implicit conversion exists from the argument type to the parameter type (both are of type `object[]`). Thus, overload resolution selects the normal form of `F`, and the argument is passed as a regular value parameter. In the second and third invocations, the normal form of `F` is not applicable because no implicit conversion exists from the argument type to the parameter type (type `object` cannot be implicitly converted to type `object[]`). However, the expanded form of `F` is applicable, so it is selected by overload resolution. As a result, a one-element `object[]` is created by the invocation, and the single element of the array is initialized with the given argument value (which itself is a reference to an `object[]`).

end example

14.6.3 Static and instance methods

When a method declaration includes a `static` modifier, that method is said to be a static method. When no `static` modifier is present, the method is said to be an instance method.

A static method does not operate on a specific instance, and it is a compile-time error to refer to `this` in a static method.

An instance method operates on a given instance of a class, and that instance can be accessed as `this` (§11.7.12).

The differences between static and instance members are discussed further in §14.3.8.

14.6.4 Virtual methods

When an instance method declaration includes a virtual modifier, that method is said to be a **virtual method**. When no virtual modifier is present, the method is said to be a **non-virtual method**.

The implementation of a non-virtual method is invariant: The implementation is the same whether the method is invoked on an instance of the class in which it is declared or an instance of a derived class. In contrast, the implementation of a virtual method can

be superseded by derived classes. The process of superseding the implementation of an inherited virtual method is known as **overriding** that method (§14.6.5).

In a virtual method invocation, the **run-time type** of the instance for which that invocation takes place determines the actual method implementation to invoke. In a non-virtual method invocation, the **compile-time type** of the instance is the determining factor. In precise terms, when a method named **M** is invoked with an argument list **A** on an instance with a compile-time type **C** and a run-time type **R** (where **R** is either **C** or a class derived from **C**), the invocation is processed as follows:

- At binding-time, overload resolution is applied to **C**, **M**, and **A**, to select a specific method **M** from the set of methods declared in and inherited by **C**. This is described in §11.7.8.2.
- Then at run-time:
 - If **M** is a non-virtual method, **M** is invoked.
 - Otherwise, **M** is a virtual method, and the most derived implementation of **M** with respect to **R** is invoked.

For every virtual method declared in or inherited by a class, there exists a **most derived implementation** of the method with respect to that class. The most derived implementation of a virtual method **M** with respect to a class **R** is determined as follows:

- If **R** contains the introducing virtual declaration of **M**, then this is the most derived implementation of **M** with respect to **R**.
- Otherwise, if **R** contains an override of **M**, then this is the most derived implementation of **M** with respect to **R**.
- Otherwise, the most derived implementation of **M** with respect to **R** is the same as the most derived implementation of **M** with respect to the direct base class of **R**.

Example: The following example illustrates the differences between virtual and non-virtual methods:

```
C#  
  
class A  
{  
    public void F() => Console.WriteLine("A.F");  
    public virtual void G() => Console.WriteLine("A.G");  
}  
  
class B : A  
{  
    public new void F() => Console.WriteLine("B.F");  
    public override void G() => Console.WriteLine("B.G");  
}
```

```

}

class Test
{
    static void Main()
    {
        B b = new B();
        A a = b;
        a.F();
        b.F();
        a.G();
        b.G();
    }
}

```

In the example, `A` introduces a non-virtual method `F` and a virtual method `G`. The class `B` introduces a *new* non-virtual method `F`, thus *hiding* the inherited `F`, and also *overrides* the inherited method `G`. The example produces the output:

Console

```

A.F
B.F
B.G
B.G

```

Notice that the statement `a.G()` invokes `B.G`, not `A.G`. This is because the run-time type of the instance (which is `B`), not the compile-time type of the instance (which is `A`), determines the actual method implementation to invoke.

end example

Because methods are allowed to hide inherited methods, it is possible for a class to contain several virtual methods with the same signature. This does not present an ambiguity problem, since all but the most derived method are hidden.

Example: In the following code

```

C#

class A
{
    public virtual void F() => Console.WriteLine("A.F");
}

class B : A
{
    public override void F() => Console.WriteLine("B.F");
}

```

```

}

class C : B
{
    public new virtual void F() => Console.WriteLine("C.F");
}

class D : C
{
    public override void F() => Console.WriteLine("D.F");
}

class Test
{
    static void Main()
    {
        D d = new D();
        A a = d;
        B b = d;
        C c = d;
        a.F();
        b.F();
        c.F();
        d.F();
    }
}

```

the `C` and `D` classes contain two virtual methods with the same signature: The one introduced by `A` and the one introduced by `C`. The method introduced by `C` hides the method inherited from `A`. Thus, the override declaration in `D` overrides the method introduced by `C`, and it is not possible for `D` to override the method introduced by `A`. The example produces the output:

Console

```

B.F
B.F
D.F
D.F

```

Note that it is possible to invoke the hidden virtual method by accessing an instance of `D` through a less derived type in which the method is not hidden.

end example

14.6.5 Override methods

When an instance method declaration includes an `override` modifier, the method is said to be an **override method**. An override method overrides an inherited virtual method with the same signature. Whereas a virtual method declaration *introduces* a new method, an override method declaration *specializes* an existing inherited virtual method by providing a new implementation of that method.

The method overridden by an override declaration is known as the **overridden base method**. For an override method `M` declared in a class `C`, the overridden base method is determined by examining each base class of `C`, starting with the direct base class of `C` and continuing with each successive direct base class, until in a given base class type at least one accessible method is located which has the same signature as `M` after substitution of type arguments. For the purposes of locating the overridden base method, a method is considered accessible if it is `public`, if it is `protected`, if it is `protected internal`, or if it is either `internal` or `private protected` and declared in the same program as `C`.

A compile-time error occurs unless all of the following are true for an override declaration:

- An overridden base method can be located as described above.
- There is exactly one such overridden base method. This restriction has effect only if the base class type is a constructed type where the substitution of type arguments makes the signature of two methods the same.
- The overridden base method is a virtual, abstract, or override method. In other words, the overridden base method cannot be static or non-virtual.
- The overridden base method is not a sealed method.
- There is an identity conversion between the return type of the overridden base method and the override method.
- The override declaration and the overridden base method have the same declared accessibility. In other words, an override declaration cannot change the accessibility of the virtual method. However, if the overridden base method is `protected internal` and it is declared in a different assembly than the assembly containing the override declaration then the override declaration's declared accessibility shall be `protected`.
- The override declaration does not specify any *type_parameter_constraints_clauses*. Instead, the constraints are inherited from the overridden base method. Constraints that are type parameters in the overridden method may be replaced by type arguments in the inherited constraint. This can lead to constraints that are not valid when explicitly specified, such as value types or sealed types.

Example: The following demonstrates how the overriding rules work for generic classes:

```
C#  
  
abstract class C<T>  
{  
    public virtual T F() {...}  
    public virtual C<T> G() {...}  
    public virtual void H(C<T> x) {...}  
}  
  
class D : C<string>  
{  
    public override string F() {...}           // Ok  
    public override C<string> G() {...}       // Ok  
    public override void H(C<T> x) {...}      // Error, should be  
C<string>  
}  
  
class E<T,U> : C<U>  
{  
    public override U F() {...}               // Ok  
    public override C<U> G() {...}           // Ok  
    public override void H(C<T> x) {...}      // Error, should be C<U>  
}
```

end example

An override declaration can access the overridden base method using a *base_access* (§11.7.13).

Example: In the following code

```
C#  
  
class A  
{  
    int x;  
  
    public virtual void PrintFields() => Console.WriteLine($"x = {x}");  
}  
  
class B : A  
{  
    int y;  
  
    public override void PrintFields()  
    {  
        base.PrintFields();  
    }  
}
```

```
        Console.WriteLine($"y = {y}");
    }
}
```

the `base.PrintFields()` invocation in `B` invokes the `PrintFields` method declared in `A`. A `base_access` disables the virtual invocation mechanism and simply treats the base method as a non-`virtual` method. Had the invocation in `B` been written `((A)this).PrintFields()`, it would recursively invoke the `PrintFields` method declared in `B`, not the one declared in `A`, since `PrintFields` is virtual and the runtime type of `((A)this)` is `B`.

end example

Only by including an `override` modifier can a method override another method. In all other cases, a method with the same signature as an inherited method simply hides the inherited method.

Example: In the following code

```
C#
class A
{
    public virtual void F() {}
}

class B : A
{
    public virtual void F() {} // Warning, hiding inherited F()
}
```

the `F` method in `B` does not include an `override` modifier and therefore does not override the `F` method in `A`. Rather, the `F` method in `B` hides the method in `A`, and a warning is reported because the declaration does not include a new modifier.

end example

Example: In the following code

```
C#
class A
{
    public virtual void F() {}
}
```

```

class B : A
{
    private new void F() {} // Hides A.F within body of B
}

class C : B
{
    public override void F() {} // Ok, overrides A.F
}

```

the `F` method in `B` hides the virtual `F` method inherited from `A`. Since the new `F` in `B` has private access, its scope only includes the class body of `B` and does not extend to `C`. Therefore, the declaration of `F` in `C` is permitted to override the `F` inherited from `A`.

end example

14.6.6 Sealed methods

When an instance method declaration includes a `sealed` modifier, that method is said to be a **sealed method**. A sealed method overrides an inherited virtual method with the same signature. A sealed method shall also be marked with the `override` modifier. Use of the `sealed` modifier prevents a derived class from further overriding the method.

Example: The example

```

C#

class A
{
    public virtual void F() => Console.WriteLine("A.F");
    public virtual void G() => Console.WriteLine("A.G");
}

class B : A
{
    public sealed override void F() => Console.WriteLine("B.F");
    public override void G() => Console.WriteLine("B.G");
}

class C : B
{
    public override void G() => Console.WriteLine("C.G");
}

```

the class `B` provides two override methods: an `F` method that has the `sealed` modifier and a `G` method that does not. `B`'s use of the `sealed` modifier prevents `C` from further overriding `F`.

end example

14.6.7 Abstract methods

When an instance method declaration includes an `abstract` modifier, that method is said to be an **abstract method**. Although an abstract method is implicitly also a virtual method, it cannot have the modifier `virtual`.

An abstract method declaration introduces a new virtual method but does not provide an implementation of that method. Instead, non-abstract derived classes are required to provide their own implementation by overriding that method. Because an abstract method provides no actual implementation, the *method_body* of an abstract method simply consists of a semicolon.

Abstract method declarations are only permitted in abstract classes ([§14.2.2.2](#)).

Example: In the following code

```
C#  
  
public abstract class Shape  
{  
    public abstract void Paint(Graphics g, Rectangle r);  
}  
  
public class Ellipse : Shape  
{  
    public override void Paint(Graphics g, Rectangle r) =>  
        g.DrawEllipse(r);  
}  
  
public class Box : Shape  
{  
    public override void Paint(Graphics g, Rectangle r) =>  
        g.DrawRect(r);  
}
```

the `Shape` class defines the abstract notion of a geometrical shape object that can paint itself. The `Paint` method is abstract because there is no meaningful default implementation. The `Ellipse` and `Box` classes are concrete `Shape` implementations.

Because these classes are non-abstract, they are required to override the `Paint` method and provide an actual implementation.

end example

It is a compile-time error for a *base_access* (§11.7.13) to reference an abstract method.

Example: In the following code

```
C#  
  
abstract class A  
{  
    public abstract void F();  
}  
  
class B : A  
{  
    // Error, base.F is abstract  
    public override void F() => base.F();  
}
```

a compile-time error is reported for the `base.F()` invocation because it references an abstract method.

end example

An abstract method declaration is permitted to override a virtual method. This allows an abstract class to force re-implementation of the method in derived classes, and makes the original implementation of the method unavailable.

Example: In the following code

```
C#  
  
class A  
{  
    public virtual void F() => Console.WriteLine("A.F");  
}  
  
abstract class B : A  
{  
    public abstract override void F();  
}  
  
class C : B  
{
```

```
public override void F() => Console.WriteLine("C.F");
}
```

class **A** declares a virtual method, class **B** overrides this method with an abstract method, and class **C** overrides the abstract method to provide its own implementation.

end example

14.6.8 External methods

When a method declaration includes an `extern` modifier, the method is said to be an **external method**. External methods are implemented externally, typically using a language other than C#. Because an external method declaration provides no actual implementation, the *method_body* of an external method simply consists of a semicolon. An external method shall not be generic.

The mechanism by which linkage to an external method is achieved, is implementation-defined.

Example: The following example demonstrates the use of the `extern` modifier and the `DllImport` attribute:

```
C#

class Path
{
    [DllImport("kernel32", SetLastError=true)]
    static extern bool CreateDirectory(string name, SecurityAttribute
sa);

    [DllImport("kernel32", SetLastError=true)]
    static extern bool RemoveDirectory(string name);

    [DllImport("kernel32", SetLastError=true)]
    static extern int GetCurrentDirectory(int bufSize, StringBuilder
buf);

    [DllImport("kernel32", SetLastError=true)]
    static extern bool SetCurrentDirectory(string name);
}
```

end example

14.6.9 Partial methods

When a method declaration includes a `partial` modifier, that method is said to be a ***partial method***. Partial methods may only be declared as members of partial types (§14.2.7), and are subject to a number of restrictions.

Partial methods may be defined in one part of a type declaration and implemented in another. The implementation is optional; if no part implements the partial method, the partial method declaration and all calls to it are removed from the type declaration resulting from the combination of the parts.

Partial methods shall not define access modifiers; they are implicitly private. Their return type shall be `void`, and their parameters shall not have the `out` modifier. The identifier `partial` is recognized as a contextual keyword (§6.4.4) in a method declaration only if it appears immediately before the `void` keyword. A partial method cannot explicitly implement interface methods.

There are two kinds of partial method declarations: If the body of the method declaration is a semicolon, the declaration is said to be a ***defining partial method declaration***. If the body is other than a semicolon, the declaration is said to be an ***implementing partial method declaration***. Across the parts of a type declaration, there may be only one defining partial method declaration with a given signature, and there may be only one implementing partial method declaration with a given signature. If an implementing partial method declaration is given, a corresponding defining partial method declaration shall exist, and the declarations shall match as specified in the following:

- The declarations shall have the same modifiers (although not necessarily in the same order), method name, number of type parameters and number of parameters.
- Corresponding parameters in the declarations shall have the same modifiers (although not necessarily in the same order) and the same types (modulo differences in type parameter names).
- Corresponding type parameters in the declarations shall have the same constraints (modulo differences in type parameter names).

An implementing partial method declaration can appear in the same part as the corresponding defining partial method declaration.

Only a defining partial method participates in overload resolution. Thus, whether or not an implementing declaration is given, invocation expressions may resolve to invocations of the partial method. Because a partial method always returns `void`, such invocation expressions will always be expression statements. Furthermore, because a partial

method is implicitly `private`, such statements will always occur within one of the parts of the type declaration within which the partial method is declared.

Note: The definition of matching defining and implementing partial method declarations does not require parameter names to match. This can produce *surprising*, albeit *well defined*, behaviour when named arguments (§11.6.2.1) are used. For example, given the defining partial method declaration for `M`:

```
C#  
  
partial class P  
{  
    static partial void M(int x);  
}
```

Then the implementing partial method declaration and invocation in other file:

```
C#  
  
partial class P  
{  
    static void Caller() => M(y: 0);  
    static partial void M(int y) {}  
}
```

is **invalid** as the invocation uses the argument name from the implementing and not the defining partial method declaration.

end note

If no part of a partial type declaration contains an implementing declaration for a given partial method, any expression statement invoking it is simply removed from the combined type declaration. Thus the invocation expression, including any subexpressions, has no effect at run-time. The partial method itself is also removed and will not be a member of the combined type declaration.

If an implementing declaration exists for a given partial method, the invocations of the partial methods are retained. The partial method gives rise to a method declaration similar to the implementing partial method declaration except for the following:

- The `partial` modifier is not included.
- The attributes in the resulting method declaration are the combined attributes of the defining and the implementing partial method declaration in unspecified

order. Duplicates are not removed.

- The attributes on the parameters of the resulting method declaration are the combined attributes of the corresponding parameters of the defining and the implementing partial method declaration in unspecified order. Duplicates are not removed.

If a defining declaration but not an implementing declaration is given for a partial method `M`, the following restrictions apply:

- It is a compile-time error to create a delegate from `M` (§11.7.15.6).
- It is a compile-time error to refer to `M` inside an anonymous function that is converted to an expression tree type (§8.6).
- Expressions occurring as part of an invocation of `M` do not affect the definite assignment state (§9.4), which can potentially lead to compile-time errors.
- `M` cannot be the entry point for an application (§7.1).

Partial methods are useful for allowing one part of a type declaration to customize the behavior of another part, e.g., one that is generated by a tool. Consider the following partial class declaration:

```
C#

partial class Customer
{
    string name;

    public string Name
    {
        get => name;
        set
        {
            OnNameChanging(value);
            name = value;
            OnNameChanged();
        }
    }

    partial void OnNameChanging(string newName);
    partial void OnNameChanged();
}

```

If this class is compiled without any other parts, the defining partial method declarations and their invocations will be removed, and the resulting combined class declaration will be equivalent to the following:

C#

```
class Customer
{
    string name;

    public string Name
    {
        get => name;
        set => name = value;
    }
}
```

Assume that another part is given, however, which provides implementing declarations of the partial methods:

C#

```
partial class Customer
{
    partial void OnNameChanging(string newName) =>
        Console.WriteLine($"Changing {name} to {newName}");

    partial void OnNameChanged() =>
        Console.WriteLine($"Changed to {name}");
}
```

Then the resulting combined class declaration will be equivalent to the following:

C#

```
class Customer
{
    string name;

    public string Name
    {
        get => name;
        set
        {
            OnNameChanging(value);
            name = value;
            OnNameChanged();
        }
    }

    void OnNameChanging(string newName) =>
        Console.WriteLine($"Changing {name} to {newName}");

    void OnNameChanged() =>
```

```
        Console.WriteLine($"Changed to {name}");
    }
```

14.6.10 Extension methods

When the first parameter of a method includes the `this` modifier, that method is said to be an *extension method*. Extension methods shall only be declared in non-generic, non-nested static classes. The first parameter of an extension method may have no modifiers other than `this`, and the parameter type may not be a pointer type.

Example: The following is an example of a static class that declares two extension methods:

```
C#

public static class Extensions
{
    public static int ToInt32(this string s) => Int32.Parse(s);

    public static T[] Slice<T>(this T[] source, int index, int count)
    {
        if (index < 0 || count < 0 || source.Length - index < count)
        {
            throw new ArgumentException();
        }
        T[] result = new T[count];
        Array.Copy(source, index, result, 0, count);
        return result;
    }
}
```

end example

An extension method is a regular static method. In addition, where its enclosing static class is in scope, an extension method may be invoked using instance method invocation syntax (§11.7.8.3), using the receiver expression as the first argument.

Example: The following program uses the extension methods declared above:

```
C#

static class Program
{
    static void Main()
    {
        string[] strings = { "1", "22", "333", "4444" };
    }
}
```

```

    foreach (string s in strings.Slice(1, 2))
    {
        Console.WriteLine(s.ToInt32());
    }
}

```

The `Slice` method is available on the `string[]`, and the `ToInt32` method is available on `string`, because they have been declared as extension methods. The meaning of the program is the same as the following, using ordinary static method calls:

```

C#

static class Program
{
    static void Main()
    {
        string[] strings = { "1", "22", "333", "4444" };
        foreach (string s in Extensions.Slice(strings, 1, 2))
        {
            Console.WriteLine(Extensions.ToInt32(s));
        }
    }
}

```

end example

14.6.11 Method body

The *method_body* of a method declaration consists of either a block body, an expression body or a semicolon.

Abstract and external method declarations do not provide a method implementation, so their method bodies simply consist of a semicolon. For any other method, the method body is a block (§12.3) that contains the statements to execute when that method is invoked.

The **effective return type** of a method is `void` if the return type is `void`, or if the method is async and the return type is `System.Threading.Tasks.Task`. Otherwise, the effective return type of a non-async method is its return type, and the effective return type of an async method with return type `System.Threading.Tasks.Task<T>` is `T`.

When the effective return type of a method is `void` and the method has a block body, `return` statements (§12.10.5) in the block shall not specify an expression. If execution of

the block of a void method completes normally (that is, control flows off the end of the method body), that method simply returns to its caller.

When the effective return type of a method is `void` and the method has an expression body, the expression `E` shall be a *statement_expression*, and the body is exactly equivalent to a statement body of the form `{ E; }`.

When the effective return type of a method is not `void` and the method has a block body, each return statement in that method's body shall specify an expression that is implicitly convertible to the effective return type. The endpoint of the method body of a value-returning method shall not be reachable. In other words, in a value-returning method with a block body, control is not permitted to flow off the end of the method body.

When the effective return type of a method is not `void` and the method has an expression body, `E`, the expression shall be implicitly convertible to the effective return type, and the body is exactly equivalent to a block body of the form `{ return E; }`.

Example: In the following code

```
C#  
  
class A  
{  
    public int F() {} // Error, return value required  
  
    public int G()  
    {  
        return 1;  
    }  
  
    public int H(bool b)  
    {  
        if (b)  
        {  
            return 1;  
        }  
        else  
        {  
            return 0;  
        }  
    }  
  
    public int I(bool b) => b ? 1 : 0;  
}
```

the value-returning **F** method results in a compile-time error because control can flow off the end of the method body. The **G** and **H** methods are correct because all possible execution paths end in a return statement that specifies a return value. The **I** method is correct, because its body is equivalent to a block with just a single return statement in it.

end example

14.7 Properties

14.7.1 General

A *property* is a member that provides access to a characteristic of an object or a class. Examples of properties include the length of a string, the size of a font, the caption of a window, the name of a customer, and so on. Properties are a natural extension of fields—both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have *accessors* that specify the statements to be executed when their values are read or written. Properties thus provide a mechanism for associating actions with the reading and writing of an object’s characteristics; furthermore, they permit such characteristics to be computed.

Properties are declared using *property_declarations*:

ANTLR

```
property_declaration
    : attributes? property_modifier* type member_name property_body
    ;

property_modifier
    : 'new'
    | 'public'
    | 'protected'
    | 'internal'
    | 'private'
    | 'static'
    | 'virtual'
    | 'sealed'
    | 'override'
    | 'abstract'
    | 'extern'
    | unsafe_modifier // unsafe code support
    ;

property_body
```

```

: '{' accessor_declarations '}' property_initializer?
| '=>' expression ';'
;

property_initializer
: '=' variable_initializer ';'
;

```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

A *property_declaration* may include a set of *attributes* (§21) and any one of the permitted kinds of declared accessibility (§14.3.6), the `new` (§14.3.5), `static` (§14.7.2), `virtual` (§14.6.4, §14.7.6), `override` (§14.6.5, §14.7.6), `sealed` (§14.6.6), `abstract` (§14.6.7, §14.7.6), and `extern` (§14.6.8) modifiers.

Property declarations are subject to the same rules as method declarations (§14.6) with regard to valid combinations of modifiers.

The *type* of a property declaration specifies the type of the property introduced by the declaration, and the *member_name* (§14.6.1) specifies the name of the property. Unless the property is an explicit interface member implementation, the *member_name* is simply an *identifier*. For an explicit interface member implementation (§17.6.2), the *member_name* consists of an *interface_type* followed by a "." and an *identifier*.

The *type* of a property shall be at least as accessible as the property itself (§7.5.5).

A *property_body* may either consist of an **accessor body** or an expression body. In an accessor body, *accessor_declarations*, which shall be enclosed in "{" and "}" tokens, declare the accessors (§14.7.3) of the property. The accessors specify the executable statements associated with reading and writing the property.

An expression body consisting of => followed by an *expression* E and a semicolon is exactly equivalent to the statement body { get { return E; } }, and can therefore only be used to specify read-only properties where the result of the get accessor is given by a single expression.

A *property_initializer* may only be given for an automatically implemented property (§14.7.4), and causes the initialization of the underlying field of such properties with the value given by the *expression*.

Even though the syntax for accessing a property is the same as that for a field, a property is not classified as a variable. Thus, it is not possible to pass a property as a `ref` or `out` argument.

When a property declaration includes an `extern` modifier, the property is said to be an *external property*. Because an external property declaration provides no actual implementation, each of its *accessor_declarations* consists of a semicolon.

14.7.2 Static and instance properties

When a property declaration includes a `static` modifier, the property is said to be a *static property*. When no `static` modifier is present, the property is said to be an *instance property*.

A static property is not associated with a specific instance, and it is a compile-time error to refer to `this` in the accessors of a static property.

An instance property is associated with a given instance of a class, and that instance can be accessed as `this` (§11.7.12) in the accessors of that property.

The differences between static and instance members are discussed further in §14.3.8.

14.7.3 Accessors

The *accessor_declarations* of a property specify the executable statements associated with reading and writing that property.

ANTLR

```
accessor_declarations
    : get_accessor_declaration set_accessor_declaration?
    | set_accessor_declaration get_accessor_declaration?
    ;

get_accessor_declaration
    : attributes? accessor_modifier? 'get' accessor_body
    ;

set_accessor_declaration
    : attributes? accessor_modifier? 'set' accessor_body
    ;

accessor_modifier
    : 'protected'
    | 'internal'
    | 'private'
    | 'protected' 'internal'
    | 'internal' 'protected'
    | 'protected' 'private'
    | 'private' 'protected'
    ;
```

```
accessor_body
  : block
  | '=>' expression ';'
  | ';'
  ;
```

The accessor declarations consist of a *get_accessor_declaration*, a *set_accessor_declaration*, or both. Each accessor declaration consists of optional attributes, an optional *accessor_modifier*, the token `get` or `set`, followed by an *accessor_body*.

The use of *accessor_modifiers* is governed by the following restrictions:

- An *accessor_modifier* shall not be used in an interface or in an explicit interface member implementation.
- For a property or indexer that has no `override` modifier, an *accessor_modifier* is permitted only if the property or indexer has both a get and set accessor, and then is permitted only on one of those accessors.
- For a property or indexer that includes an `override` modifier, an accessor shall match the *accessor_modifier*, if any, of the accessor being overridden.
- The *accessor_modifier* shall declare an accessibility that is strictly more restrictive than the declared accessibility of the property or indexer itself. To be precise:
 - If the property or indexer has a declared accessibility of `public`, the accessibility declared by *accessor_modifier* may be either `private protected`, `protected internal`, `internal`, `protected`, or `private`.
 - If the property or indexer has a declared accessibility of `protected internal`, the accessibility declared by *accessor_modifier* may be either `private protected`, `protected private`, `internal`, `protected`, or `private`.
 - If the property or indexer has a declared accessibility of `internal` or `protected`, the accessibility declared by *accessor_modifier* shall be either `private protected` or `private`.
 - If the property or indexer has a declared accessibility of `private protected`, the accessibility declared by *accessor_modifier* shall be `private`.
 - If the property or indexer has a declared accessibility of `private`, no *accessor_modifier* may be used.

For `abstract` and `extern` properties, the *accessor_body* for each accessor specified is simply a semicolon. A non-abstract, non-extern property may also have the *accessor_body* for all accessors specified be a semicolon, in which case it is an **automatically implemented property** (§14.7.4). An automatically implemented property

shall have at least a get accessor. For the accessors of any other non-abstract, non-extern property, the *accessor_body* is either

- a *block* that specifies the statements to be executed when the corresponding accessor is invoked; or
- an expression body, which consists of `=>` followed by an *expression* and a semicolon, and denotes a single expression to be executed when the corresponding accessor is invoked.

A get accessor corresponds to a parameterless method with a return value of the property type. Except as the target of an assignment, when a property is referenced in an expression, the get accessor of the property is invoked to compute the value of the property (§11.2.2). The body of a get accessor shall conform to the rules for value-returning methods described in §14.6.11. In particular, all `return` statements in the body of a get accessor shall specify an expression that is implicitly convertible to the property type. Furthermore, the endpoint of a get accessor shall not be reachable.

A `set` accessor corresponds to a method with a single value parameter of the property type and a `void` return type. The implicit parameter of a `set` accessor is always named `value`. When a property is referenced as the target of an assignment (§11.19), or as the operand of `++` or `--` (§11.7.14, §11.8.6), the `set` accessor is invoked with an argument that provides the new value (§11.19.2). The body of a `set` accessor shall conform to the rules for `void` methods described in §14.6.11. In particular, return statements in the `set` accessor body are not permitted to specify an expression. Since a `set` accessor implicitly has a parameter named `value`, it is a compile-time error for a local variable or constant declaration in a `set` accessor to have that name.

Based on the presence or absence of the get and set accessors, a property is classified as follows:

- A property that includes both a get accessor and a set accessor is said to be a ***read-write property***.
- A property that has only a get accessor is said to be a ***read-only property***. It is a compile-time error for a read-only property to be the target of an assignment.
- A property that has only a set accessor is said to be a ***write-only property***. Except as the target of an assignment, it is a compile-time error to reference a write-only property in an expression.

Note: The pre- and postfix `++` and `--` operators and compound assignment operators cannot be applied to write-only properties, since these operators read the old value of their operand before they write the new one. *end note*

Example: In the following code

```
C#  
  
public class Button : Control  
{  
    private string caption;  
  
    public string Caption  
    {  
        get => caption;  
        set  
        {  
            if (caption != value)  
            {  
                caption = value;  
                Repaint();  
            }  
        }  
    }  
  
    public override void Paint(Graphics g, Rectangle r)  
    {  
        // Painting code goes here  
    }  
}
```

the `Button` control declares a public `Caption` property. The get accessor of the `Caption` property returns the `string` stored in the private `caption` field. The set accessor checks if the new value is different from the current value, and if so, it stores the new value and repaints the control. Properties often follow the pattern shown above: The get accessor simply returns a value stored in a `private` field, and the set accessor modifies that `private` field and then performs any additional actions required to update fully the state of the object. Given the `Button` class above, the following is an example of use of the `Caption` property:

```
C#  
  
Button okButton = new Button();  
okButton.Caption = "OK"; // Invokes set accessor  
string s = okButton.Caption; // Invokes get accessor
```

Here, the set accessor is invoked by assigning a value to the property, and the get accessor is invoked by referencing the property in an expression.

end example

The get and set accessors of a property are not distinct members, and it is not possible to declare the accessors of a property separately.

Example: The example

```
C#  
  
class A  
{  
    private string name;  
  
    // Error, duplicate member name  
    public string Name  
    {  
        get => name;  
    }  
  
    // Error, duplicate member name  
    public string Name  
    {  
        set => name = value;  
    }  
}
```

does not declare a single read-write property. Rather, it declares two properties with the same name, one read-only and one write-only. Since two members declared in the same class cannot have the same name, the example causes a compile-time error to occur.

end example

When a derived class declares a property by the same name as an inherited property, the derived property hides the inherited property with respect to both reading and writing.

Example: In the following code

```
C#  
  
class A  
{  
    public int P  
    {  
        set {...}  
    }  
}  
  
class B : A  
{
```

```

public new int P
{
    get {...}
}
}

```

the `P` property in `B` hides the `P` property in `A` with respect to both reading and writing. Thus, in the statements

C#

```

B b = new B();
b.P = 1;           // Error, B.P is read-only
((A)b).P = 1;     // Ok, reference to A.P

```

the assignment to `b.P` causes a compile-time error to be reported, since the read-only `P` property in `B` hides the write-only `P` property in `A`. Note, however, that a cast can be used to access the hidden `P` property.

end example

Unlike public fields, properties provide a separation between an object's internal state and its public interface.

Example: Consider the following code, which uses a `Point` struct to represent a location:

C#

```

class Label
{
    private int x, y;
    private string caption;

    public Label(int x, int y, string caption)
    {
        this.x = x;
        this.y = y;
        this.caption = caption;
    }

    public int X => x;
    public int Y => y;
    public Point Location => new Point(x, y);
    public string Caption => caption;
}

```

Here, the `Label` class uses two `int` fields, `x` and `y`, to store its location. The location is publicly exposed both as an `X` and a `Y` property and as a `Location` property of type `Point`. If, in a future version of `Label`, it becomes more convenient to store the location as a `Point` internally, the change can be made without affecting the public interface of the class:

```
C#  
  
class Label  
{  
    private Point location;  
    private string caption;  
  
    public Label(int x, int y, string caption)  
    {  
        this.location = new Point(x, y);  
        this.caption = caption;  
    }  
  
    public int X => location.x;  
    public int Y => location.y;  
    public Point Location => location;  
    public string Caption => caption;  
}
```

Had `x` and `y` instead been `public readonly` fields, it would have been impossible to make such a change to the `Label` class.

end example

Note: Exposing state through properties is not necessarily any less efficient than exposing fields directly. In particular, when a property is non-virtual and contains only a small amount of code, the execution environment might replace calls to accessors with the actual code of the accessors. This process is known as *inlining*, and it makes property access as efficient as field access, yet preserves the increased flexibility of properties. *end note*

Example: Since invoking a get accessor is conceptually equivalent to reading the value of a field, it is considered bad programming style for get accessors to have observable side-effects. In the example

```
C#  
  
class Counter  
{  
    private int next;
```

```
public int Next => next++;  
}
```

the value of the `Next` property depends on the number of times the property has previously been accessed. Thus, accessing the property produces an observable side effect, and the property should be implemented as a method instead.

The “no side-effects” convention for get accessors doesn’t mean that get accessors should always be written simply to return values stored in fields. Indeed, get accessors often compute the value of a property by accessing multiple fields or invoking methods. However, a properly designed get accessor performs no actions that cause observable changes in the state of the object.

end example

Properties can be used to delay initialization of a resource until the moment it is first referenced.

Example:

C#

```
public class Console  
{  
    private static TextReader reader;  
    private static TextWriter writer;  
    private static TextWriter error;  
  
    public static TextReader In  
    {  
        get  
        {  
            if (reader == null)  
            {  
                reader = new StreamReader(Console.OpenStandardInput());  
            }  
            return reader;  
        }  
    }  
  
    public static TextWriter Out  
    {  
        get  
        {  
            if (writer == null)  
            {  
                writer = new StreamWriter(Console.OpenStandardOutput());  
            }  
        }  
    }  
}
```

```

        return writer;
    }
}

public static TextWriter Error
{
    get
    {
        if (error == null)
        {
            error = new StreamWriter(Console.OpenStandardError());
        }
        return error;
    }
}
...
}

```

The `Console` class contains three properties, `In`, `Out`, and `Error`, that represent the standard input, output, and error devices, respectively. By exposing these members as properties, the `Console` class can delay their initialization until they are actually used. For example, upon first referencing the `Out` property, as in

```

C#
Console.Out.WriteLine("hello, world");

```

the underlying `TextWriter` for the output device is created. However, if the application makes no reference to the `In` and `Error` properties, then no objects are created for those devices.

end example

14.7.4 Automatically implemented properties

An automatically implemented property (or auto-property for short), is a non-abstract, non-extern property with semicolon-only accessor bodies. Auto-properties shall have a get accessor and may optionally have a set accessor.

When a property is specified as an automatically implemented property, a hidden backing field is automatically available for the property, and the accessors are implemented to read from and write to that backing field. The hidden backing field is inaccessible, it can be read and written only through the automatically implemented property accessors, even within the containing type. If the auto-property has no set accessor, the backing field is considered `readonly` (§14.5.3). Just like a `readonly` field, a

read-only auto-property may also be assigned to in the body of a constructor of the enclosing class. Such an assignment assigns directly to the read-only backing field of the property.

An auto-property may optionally have a *property_initializer*, which is applied directly to the backing field as a *variable_initializer* (§16.7).

Example:

```
C#  
  
public class Point  
{  
    public int X { get; set; } // Automatically implemented  
    public int Y { get; set; } // Automatically implemented  
}
```

is equivalent to the following declaration:

```
C#  
  
public class Point  
{  
    private int x;  
    private int y;  
  
    public int X { get { return x; } set { x = value; } }  
    public int Y { get { return y; } set { y = value; } }  
}
```

end example

Example: In the following

```
C#  
  
public class ReadOnlyPoint  
{  
    public int X { get; }  
    public int Y { get; }  
  
    public ReadOnlyPoint(int x, int y)  
    {  
        X = x;  
        Y = y;  
    }  
}
```

is equivalent to the following declaration:

```
C#  
  
public class ReadOnlyPoint  
{  
    private readonly int __x;  
    private readonly int __y;  
    public int X { get { return __x; } }  
    public int Y { get { return __y; } }  
  
    public ReadOnlyPoint(int x, int y)  
    {  
        __x = x;  
        __y = y;  
    }  
}
```

The assignments to the read-only field are valid, because they occur within the constructor.

end example

Although the backing field is hidden, that field may have field-targeted attributes applied directly to it via the automatically implemented property's *property_declaration* (§14.7.1).

Example: The following code

```
C#  
  
[Serializable]  
public class Foo  
{  
    [field: NonSerialized]  
    public string MySecret { get; set; }  
}
```

results in the field-targeted attribute `NonSerialized` being applied to the compiler-generated backing field, as if the code had been written as follows:

```
C#  
  
[Serializable]  
public class Foo  
{  
    [NonSerialized]  
    private string _mySecretBackingField;
```

```
public string MySecret
{
    get { return _mySecretBackingField; }
    set { _mySecretBackingField = value; }
}
```

end example

14.7.5 Accessibility

If an accessor has an *accessor_modifier*, the accessibility domain (§7.5.3) of the accessor is determined using the declared accessibility of the *accessor_modifier*. If an accessor does not have an *accessor_modifier*, the accessibility domain of the accessor is determined from the declared accessibility of the property or indexer.

The presence of an *accessor_modifier* never affects member lookup (§11.5) or overload resolution (§11.6.4). The modifiers on the property or indexer always determine which property or indexer is bound to, regardless of the context of the access.

Once a particular property or indexer has been selected, the accessibility domains of the specific accessors involved are used to determine if that usage is valid:

- If the usage is as a value (§11.2.2), the get accessor shall exist and be accessible.
- If the usage is as the target of a simple assignment (§11.19.2), the set accessor shall exist and be accessible.
- If the usage is as the target of compound assignment (§11.19.3), or as the target of the ++ or -- operators (§11.7.14, §11.8.6), both the get accessors and the set accessor shall exist and be accessible.

Example: In the following example, the property `A.Text` is hidden by the property `B.Text`, even in contexts where only the set accessor is called. In contrast, the property `B.Count` is not accessible to class `M`, so the accessible property `A.Count` is used instead.

C#

```
class A
{
    public string Text
    {
        get => "hello";
        set { }
    }
}
```

```

public int Count
{
    get => 5;
    set { }
}
}

class B : A
{
    private string text = "goodbye";
    private int count = 0;

    public new string Text
    {
        get => text;
        protected set => text = value;
    }

    protected new int Count
    {
        get => count;
        set => count = value;
    }
}

class M
{
    static void Main()
    {
        B b = new B();
        b.Count = 12;           // Calls A.Count set accessor
        int i = b.Count;       // Calls A.Count get accessor
        b.Text = "howdy";     // Error, B.Text set accessor not accessible
        string s = b.Text;    // Calls B.Text get accessor
    }
}

```

end example

An accessor that is used to implement an interface shall not have an *accessor_modifier*. If only one accessor is used to implement an interface, the other accessor may be declared with an *accessor_modifier*:

Example:

```

C#

public interface I
{
    string Prop { get; }
}

```

```

public class C : I
{
    public string Prop
    {
        get => "April";    // Must not have a modifier here
        internal set {...} // Ok, because I.Prop has no set accessor
    }
}

```

end example

14.7.6 Virtual, sealed, override, and abstract accessors

A virtual property declaration specifies that the accessors of the property are virtual. The `virtual` modifier applies to all non-private accessors of a property. When an accessor of a virtual property has the private *accessor_modifier*, the `private` accessor is implicitly not virtual.

An abstract property declaration specifies that the accessors of the property are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the property. Because an accessor for an abstract property declaration provides no actual implementation, its *accessor_body* simply consists of a semicolon. An abstract property shall not have a `private` accessor.

A property declaration that includes both the `abstract` and `override` modifiers specifies that the property is abstract and overrides a base property. The accessors of such a property are also abstract.

Abstract property declarations are only permitted in abstract classes (§14.2.2.2). The accessors of an inherited virtual property can be overridden in a derived class by including a property declaration that specifies an `override` directive. This is known as an **overriding property declaration**. An overriding property declaration does not declare a new property. Instead, it simply specializes the implementations of the accessors of an existing virtual property.

The override declaration and the overridden base property are required to have the same declared accessibility. In other words, an override declaration may not change the accessibility of the base property. However, if the overridden base property is protected internal and it is declared in a different assembly than the assembly containing the override declaration then the override declaration's declared accessibility shall be protected. If the inherited property has only a single accessor (i.e., if the inherited

property is read-only or write-only), the overriding property shall include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors. There shall be an identity conversion between the type of the overriding and the inherited property.

An overriding property declaration may include the `sealed` modifier. Use of this modifier prevents a derived class from further overriding the property. The accessors of a sealed property are also sealed.

Except for differences in declaration and invocation syntax, `virtual`, `sealed`, `override`, and `abstract` accessors behave exactly like `virtual`, `sealed`, `override` and `abstract` methods. Specifically, the rules described in §14.6.4, §14.6.5, §14.6.6, and §14.6.7 apply as if accessors were methods of a corresponding form:

- A `get` accessor corresponds to a parameterless method with a return value of the property type and the same modifiers as the containing property.
- A `set` accessor corresponds to a method with a single value parameter of the property type, a void return type, and the same modifiers as the containing property.

Example: In the following code

```
C#  
  
abstract class A  
{  
    int y;  
  
    public virtual int X  
    {  
        get => 0;  
    }  
  
    public virtual int Y  
    {  
        get => y;  
        set => y = value;  
    }  
  
    public abstract int Z { get; set; }  
}
```

`X` is a virtual read-only property, `Y` is a virtual read-write property, and `Z` is an abstract read-write property. Because `Z` is abstract, the containing class `A` shall also be declared abstract.

A class that derives from `A` is shown below:

```
C#  
  
class B : A  
{  
    int z;  
  
    public override int X  
    {  
        get => base.X + 1;  
    }  
  
    public override int Y  
    {  
        set => base.Y = value < 0 ? 0: value;  
    }  
  
    public override int Z  
    {  
        get => z;  
        set => z = value;  
    }  
}
```

Here, the declarations of `X`, `Y`, and `Z` are overriding property declarations. Each property declaration exactly matches the accessibility modifiers, type, and name of the corresponding inherited property. The get accessor of `X` and the set accessor of `Y` use the base keyword to access the inherited accessors. The declaration of `Z` overrides both abstract accessors—thus, there are no outstanding `abstract` function members in `B`, and `B` is permitted to be a non-abstract class.

end example

When a property is declared as an override, any overridden accessors shall be accessible to the overriding code. In addition, the declared accessibility of both the property or indexer itself, and of the accessors, shall match that of the overridden member and accessors.

Example:

```
C#  
  
public class B  
{  
    public virtual int P  
    {  
        get {...}    }  
}
```

```

        protected set {...}
    }
}

public class D: B
{
    public override int P
    {
        get {...}           // Must not have a modifier here
        protected set {...} // Must specify protected here
    }
}

```

end example

14.8 Events

14.8.1 General

An *event* is a member that enables an object or class to provide notifications. Clients can attach executable code for events by supplying *event handlers*.

Events are declared using *event_declarations*:

ANTLR

```

event_declaration
: attributes? event_modifier* 'event' type variable_declarators ';'
| attributes? event_modifier* 'event' type member_name
  '{' event_accessor_declarations '}'
;

event_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'static'
| 'virtual'
| 'sealed'
| 'override'
| 'abstract'
| 'extern'
| unsafe_modifier // unsafe code support
;

event_accessor_declarations
: add_accessor_declaration remove_accessor_declaration
| remove_accessor_declaration add_accessor_declaration

```

```

;

add_accessor_declaration
  : attributes? 'add' block
  ;

remove_accessor_declaration
  : attributes? 'remove' block
  ;

```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

An *event_declaration* may include a set of *attributes* (§21) and any one of the permitted kinds of declared accessibility (§14.3.6), the `new` (§14.3.5), `static` (§14.6.3, §14.8.4), `virtual` (§14.6.4, §14.8.5), `override` (§14.6.5, §14.8.5), `sealed` (§14.6.6), `abstract` (§14.6.7, §14.8.5), and `extern` (§14.6.8) modifiers.

Event declarations are subject to the same rules as method declarations (§14.6) with regard to valid combinations of modifiers.

The *type* of an event declaration shall be a *delegate_type* (§8.2.8), and that *delegate_type* shall be at least as accessible as the event itself (§7.5.5).

An event declaration can include *event_accessor_declarations*. However, if it does not, for non-extern, non-abstract events, the compiler shall supply them automatically (§14.8.2); for `extern` events, the accessors are provided externally.

An event declaration that omits *event_accessor_declarations* defines one or more events—one for each of the *variable_declarators*. The attributes and modifiers apply to all of the members declared by such an *event_declaration*.

It is a compile-time error for an *event_declaration* to include both the `abstract` modifier and *event_accessor_declarations*.

When an event declaration includes an `extern` modifier, the event is said to be an **external event**. Because an external event declaration provides no actual implementation, it is an error for it to include both the `extern` modifier and *event_accessor_declarations*.

It is a compile-time error for a *variable_declarator* of an event declaration with an `abstract` or `external` modifier to include a *variable_initializer*.

An event can be used as the left-hand operand of the `+=` and `-=` operators. These operators are used, respectively, to attach event handlers to, or to remove event

handlers from an event, and the access modifiers of the event control the contexts in which such operations are permitted.

The only operations that are permitted on an event by code that is outside the type in which that event is declared, are `+=` and `-=`. Therefore, while such code can add and remove handlers for an event, it cannot directly obtain or modify the underlying list of event handlers.

In an operation of the form `x += y` or `x -= y`, when `x` is an event the result of the operation has type `void` (§11.19.4) (as opposed to having the type of `x`, with the value of `x` after the assignment, as for other the `+=` and `-=` operators defined on non-event types). This prevents external code from indirectly examining the underlying delegate of an event.

Example: The following example shows how event handlers are attached to instances of the `Button` class:

C#

```
public delegate void EventHandler(object sender, EventArgs e);

public class Button : Control
{
    public event EventHandler Click;
}

public class LoginDialog : Form
{
    Button okButton;
    Button cancelButton;

    public LoginDialog()
    {
        okButton = new Button(...);
        okButton.Click += new EventHandler(OkButtonClick);
        cancelButton = new Button(...);
        cancelButton.Click += new EventHandler(CancelButtonClick);
    }

    void OkButtonClick(object sender, EventArgs e)
    {
        // Handle okButton.Click event
    }

    void CancelButtonClick(object sender, EventArgs e)
    {
        // Handle cancelButton.Click event
    }
}
```

Here, the `LoginDialog` instance constructor creates two `Button` instances and attaches event handlers to the `Click` events.

end example

14.8.2 Field-like events

Within the program text of the class or struct that contains the declaration of an event, certain events can be used like fields. To be used in this way, an event shall not be abstract or extern, and shall not explicitly include *event_accessor_declarations*. Such an event can be used in any context that permits a field. The field contains a delegate (§19), which refers to the list of event handlers that have been added to the event. If no event handlers have been added, the field contains `null`.

Example: In the following code

```
C#

public delegate void EventHandler(object sender, EventArgs e);

public class Button : Control
{
    public event EventHandler Click;

    protected void OnClick(EventArgs e)
    {
        EventHandler handler = Click;
        if (handler != null)
        {
            handler(this, e);
        }
    }

    public void Reset() => Click = null;
}

```

`Click` is used as a field within the `Button` class. As the example demonstrates, the field can be examined, modified, and used in delegate invocation expressions. The `OnClick` method in the `Button` class “raises” the `Click` event. The notion of raising an event is precisely equivalent to invoking the delegate represented by the event—thus, there are no special language constructs for raising events. Note that the delegate invocation is preceded by a check that ensures the delegate is non-null and that the check is made on a local copy to ensure thread safety.

Outside the declaration of the `Button` class, the `Click` member can only be used on the left-hand side of the `+=` and `-=` operators, as in

```
C#
```

```
b.Click += new EventHandler(...);
```

which appends a delegate to the invocation list of the `Click` event, and

```
C#
```

```
Click -= new EventHandler(...);
```

which removes a delegate from the invocation list of the `Click` event.

end example

When compiling a field-like event, the compiler automatically creates storage to hold the delegate, and creates accessors for the event that add or remove event handlers to the delegate field. The addition and removal operations are thread safe, and may (but are not required to) be done while holding the lock (§9.4.4.19) in the containing object for an instance event, or the type `object` (§11.7.15.7) for a static event.

Note: Thus, an instance event declaration of the form:

```
C#
```

```
class X
{
    public event D Ev;
}
```

shall be compiled to something equivalent to:

```
C#
```

```
class X
{
    private D __Ev; // field to hold the delegate

    public event D Ev
    {
        add
        {
            /* Add the delegate in a thread safe way */
        }
    }
}
```

```

        remove
        {
            /* Remove the delegate in a thread safe way */
        }
    }
}

```

Within the class `X`, references to `Ev` on the left-hand side of the `+=` and `-=` operators cause the add and remove accessors to be invoked. All other references to `Ev` are compiled to reference the hidden field `__Ev` instead (§11.7.6). The name “`__Ev`” is arbitrary; the hidden field could have any name or no name at all.

end note

14.8.3 Event accessors

Note: Event declarations typically omit *event_accessor_declarations*, as in the `Button` example above. For example, they might be included if the storage cost of one field per event is not acceptable. In such cases, a class can include *event_accessor_declarations* and use a private mechanism for storing the list of event handlers. *end note*

The *event_accessor_declarations* of an event specify the executable statements associated with adding and removing event handlers.

The accessor declarations consist of an *add_accessor_declaration* and a *remove_accessor_declaration*. Each accessor declaration consists of the token add or remove followed by a *block*. The *block* associated with an *add_accessor_declaration* specifies the statements to execute when an event handler is added, and the *block* associated with a *remove_accessor_declaration* specifies the statements to execute when an event handler is removed.

Each *add_accessor_declaration* and *remove_accessor_declaration* corresponds to a method with a single value parameter of the event type, and a `void` return type. The implicit parameter of an `event` accessor is named `value`. When an event is used in an event assignment, the appropriate `event` accessor is used. Specifically, if the assignment operator is `+=` then the add accessor is used, and if the assignment operator is `-=` then the remove accessor is used. In either case, the right-hand operand of the assignment operator is used as the argument to the `event` accessor. The block of an *add_accessor_declaration* or a *remove_accessor_declaration* shall conform to the rules for `void` methods described in §14.6.9. In particular, `return` statements in such a block are not permitted to specify an expression.

Since an `event` accessor implicitly has a parameter named `value`, it is a compile-time error for a local variable or constant declared in an `event` accessor to have that name.

Example: In the following code

```
C#

class Control : Component
{
    // Unique keys for events
    static readonly object mouseDownEventKey = new object();
    static readonly object mouseUpEventKey = new object();

    // Return event handler associated with key
    protected Delegate GetEventHandler(object key) {...}

    // Add event handler associated with key
    protected void AddEventHandler(object key, Delegate handler) {...}

    // Remove event handler associated with key
    protected void RemoveEventHandler(object key, Delegate handler)
    {...}

    // MouseDown event
    public event MouseEventHandler MouseDown
    {
        add { AddEventHandler(mouseDownEventKey, value); }
        remove { RemoveEventHandler(mouseDownEventKey, value); }
    }

    // MouseUp event
    public event MouseEventHandler MouseUp
    {
        add { AddEventHandler(mouseUpEventKey, value); }
        remove { RemoveEventHandler(mouseUpEventKey, value); }
    }

    // Invoke the MouseUp event
    protected void OnMouseUp(MouseEventArgs args)
    {
        MouseEventHandler handler;
        handler = (MouseEventHandler)GetEventHandler(mouseUpEventKey);
        if (handler != null)
        {
            handler(this, args);
        }
    }
}
```

the `Control` class implements an internal storage mechanism for events. The `AddEventHandler` method associates a delegate value with a key, the `GetEventHandler` method returns the delegate currently associated with a key, and the `RemoveEventHandler` method removes a delegate as an event handler for the specified event. Presumably, the underlying storage mechanism is designed such that there is no cost for associating a null delegate value with a key, and thus unhandled events consume no storage.

end example

14.8.4 Static and instance events

When an event declaration includes a `static` modifier, the event is said to be a **static event**. When no `static` modifier is present, the event is said to be an **instance event**.

A static event is not associated with a specific instance, and it is a compile-time error to refer to `this` in the accessors of a static event.

An instance event is associated with a given instance of a class, and this instance can be accessed as `this` (§11.7.12) in the accessors of that event.

The differences between static and instance members are discussed further in §14.3.8.

14.8.5 Virtual, sealed, override, and abstract accessors

A virtual event declaration specifies that the accessors of that event are virtual. The `virtual` modifier applies to both accessors of an event.

An abstract event declaration specifies that the accessors of the event are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the event. Because an accessor for an abstract event declaration provides no actual implementation, it shall not provide *event_accessor_declarations*.

An event declaration that includes both the `abstract` and `override` modifiers specifies that the event is abstract and overrides a base event. The accessors of such an event are also abstract.

Abstract event declarations are only permitted in abstract classes (§14.2.2.2).

The accessors of an inherited virtual event can be overridden in a derived class by including an event declaration that specifies an `override` modifier. This is known as an

overriding event declaration. An overriding event declaration does not declare a new event. Instead, it simply specializes the implementations of the accessors of an existing virtual event.

An overriding event declaration shall specify the exact same accessibility modifiers and name as the overridden event, there shall be an identity conversion between the type of the overriding and the overridden event, and both the add and remove accessors shall be specified within the declaration.

An overriding event declaration can include the `sealed` modifier. Use of `this` modifier prevents a derived class from further overriding the event. The accessors of a sealed event are also sealed.

It is a compile-time error for an overriding event declaration to include a `new` modifier.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in §14.6.4, §14.6.5, §14.6.6, and §14.6.7 apply as if accessors were methods of a corresponding form. Each accessor corresponds to a method with a single value parameter of the event type, a `void` return type, and the same modifiers as the containing event.

14.9 Indexers

An **indexer** is a member that enables an object to be indexed in the same way as an array. Indexers are declared using *indexer_declarations*:

ANTLR

```
indexer_declaration
: attributes? indexer_modifier* indexer_declarator indexer_body
;

indexer_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'virtual'
| 'sealed'
| 'override'
| 'abstract'
| 'extern'
| unsafe_modifier // unsafe code support
;
```

```

indexer_declarator
: type 'this' '[' formal_parameter_list ']'
| type interface_type '.' 'this' '[' formal_parameter_list ']'
;

indexer_body
: '{' accessor_declarations '}'
| '=>' expression ';'
;

```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

An *indexer_declaration* may include a set of *attributes* (§21) and any one of the permitted kinds of declared accessibility (§14.3.6), the `new` (§14.3.5), `virtual` (§14.6.4), `override` (§14.6.5), `sealed` (§14.6.6), `abstract` (§14.6.7), and `extern` (§14.6.8) modifiers.

Indexer declarations are subject to the same rules as method declarations (§14.6) with regard to valid combinations of modifiers, with the one exception being that the `static` modifier is not permitted on an indexer declaration.

The modifiers `virtual`, `override`, and `abstract` are mutually exclusive except in one case. The `abstract` and `override` modifiers may be used together so that an abstract indexer can override a virtual one.

The *type* of an indexer declaration specifies the element type of the indexer introduced by the declaration.

Note: As indexers are designed to be used in array element-like contexts, the term *element type* as defined for an array is also used with an indexer. *end note*

Unless the indexer is an explicit interface member implementation, the *type* is followed by the keyword `this`. For an explicit interface member implementation, the *type* is followed by an *interface_type*, a ".", and the keyword `this`. Unlike other members, indexers do not have user-defined names.

The *formal_parameter_list* specifies the parameters of the indexer. The formal parameter list of an indexer corresponds to that of a method (§14.6.2), except that at least one parameter shall be specified, and that the `this`, `ref`, and `out` parameter modifiers are not permitted.

The *type* of an indexer and each of the types referenced in the *formal_parameter_list* shall be at least as accessible as the indexer itself (§7.5.5).

An *indexer_body* may either consist of an accessor body (§14.7.1) or an expression body (§14.6.1). In an accessor body, *accessor_declarations*, which shall be enclosed in “{” and “}” tokens, declare the accessors (§14.7.3) of the indexer. The accessors specify the executable statements associated with reading and writing indexer elements.

Based on the presence or absence of get and set accessors, an indexer is classified as follows:

- An indexer that includes both a get accessor and a set accessor is said to be a ***read-write indexer***.
- An indexer that has only a get accessor is said to be a ***read-only indexer***. It is a compile-time error for a read-only indexer to be the target of an assignment.
- An indexer that has only a set accessor is said to be a ***write-only indexer***. Except as the target of an assignment, it is a compile-time error to reference a write-only indexer in an expression.

An expression body consisting of “=>” followed by an expression *E* and a semicolon is exactly equivalent to the block body { get { return *E*; } }, and can therefore only be used to specify read-only indexers where the result of the get accessor is given by a single expression.

Even though the syntax for accessing an indexer element is the same as that for an array element, an indexer element is not classified as a variable. Thus, it is not possible to pass an indexer element as a `ref` or `out` argument.

The *formal_parameter_list* of an indexer defines the signature (§7.6) of the indexer. Specifically, the signature of an indexer consists of the number and types of its formal parameters. The element type and names of the formal parameters are not part of an indexer’s signature.

The signature of an indexer shall differ from the signatures of all other indexers declared in the same class.

Indexers and properties are very similar in concept, but differ in the following ways:

- A property is identified by its name, whereas an indexer is identified by its signature.
- A property is accessed through a *simple_name* (§11.7.4) or a *member_access* (§11.7.6), whereas an indexer element is accessed through an *element_access* (§11.7.10.3).
- A property can be a static member, whereas an indexer is always an instance member.

- A `get` accessor of a property corresponds to a method with no parameters, whereas a `get` accessor of an indexer corresponds to a method with the same formal parameter list as the indexer.
- A `set` accessor of a property corresponds to a method with a single parameter named `value`, whereas a `set` accessor of an indexer corresponds to a method with the same formal parameter list as the indexer, plus an additional parameter named `value`.
- It is a compile-time error for an indexer accessor to declare a local variable or local constant with the same name as an indexer parameter.
- In an overriding property declaration, the inherited property is accessed using the syntax `base.P`, where `P` is the property name. In an overriding indexer declaration, the inherited indexer is accessed using the syntax `base[E]`, where `E` is a comma-separated list of expressions.
- There is no concept of an “automatically implemented indexer”. It is an error to have a non-abstract, non-external indexer with semicolon accessors.

Aside from these differences, all rules defined in §14.7.3 and §14.7.4 apply to indexer accessors as well as to property accessors.

When an indexer declaration includes an `extern` modifier, the indexer is said to be an **external indexer**. Because an external indexer declaration provides no actual implementation, each of its *accessor_declarations* consists of a semicolon.

Example: The example below declares a `BitArray` class that implements an indexer for accessing the individual bits in the bit array.

```
C#
class BitArray
{
    int[] bits;
    int length;

    public BitArray(int length)
    {
        if (length < 0)
        {
            throw new ArgumentException();
        }
        bits = new int[((length - 1) >> 5) + 1];
        this.length = length;
    }

    public int Length => length;

    public bool this[int index]
```

```

{
    get
    {
        if (index < 0 || index >= length)
        {
            throw new IndexOutOfRangeException();
        }
        return (bits[index >> 5] & 1 << index) != 0;
    }
    set
    {
        if (index < 0 || index >= length)
        {
            throw new IndexOutOfRangeException();
        }
        if (value)
        {
            bits[index >> 5] |= 1 << index;
        }
        else
        {
            bits[index >> 5] &= ~(1 << index);
        }
    }
}
}
}

```

An instance of the `BitArray` class consumes substantially less memory than a corresponding `bool[]` (since each value of the former occupies only one bit instead of the latter's one `byte`), but it permits the same operations as a `bool[]`.

The following `CountPrimes` class uses a `BitArray` and the classical "sieve" algorithm to compute the number of primes between 2 and a given maximum:

C#

```

class Grid
{
    const int NumRows = 26;
    const int NumCols = 10;
    int[,] cells = new int[NumRows, NumCols];

    public int this[char row, int col]
    {
        get
        {
            row = Char.ToUpper(row);
            if (row < 'A' || row > 'Z')
            {
                throw new ArgumentOutOfRangeException("row");
            }
            if (col < 0 || col >= NumCols)

```

```

        {
            throw new ArgumentOutOfRangeException ("col");
        }
        return cells[row - 'A', col];
    }
    set
    {
        row = Char.ToUpper(row);
        if (row < 'A' || row > 'Z')
        {
            throw new ArgumentOutOfRangeException ("row");
        }
        if (col < 0 || col >= NumCols)
        {
            throw new ArgumentOutOfRangeException ("col");
        }
        cells[row - 'A', col] = value;
    }
}
}

```

end example

14.10 Operators

14.10.1 General

An *operator* is a member that defines the meaning of an expression operator that can be applied to instances of the class. Operators are declared using *operator_declarations*:

ANTLR

```

operator_declaration
    : attributes? operator_modifier+ operator_declarator operator_body
    ;

```

```

operator_modifier
    : 'public'
    | 'static'
    | 'extern'
    | unsafe_modifier // unsafe code support
    ;

```

```

operator_declarator
    : unary_operator_declarator
    | binary_operator_declarator
    | conversion_operator_declarator
    ;

```

```

unary_operator_declarator

```

```

: type 'operator' overloadable_unary_operator '(' fixed_parameter ')'
;

overloadable_unary_operator
: '+' | '-' | '!' | '~' | '++' | '--' | 'true' | 'false'
;

binary_operator_declarator
: type 'operator' overloadable_binary_operator
  '(' fixed_parameter ',' fixed_parameter ')'
;

overloadable_binary_operator
: '+' | '-' | '*' | '/' | '%' | '&' | '|' | '^' | '<<'
  | right_shift | '==' | '!=' | '>' | '<' | '>=' | '<='
;

conversion_operator_declarator
: 'implicit' 'operator' type '(' fixed_parameter ')'
  | 'explicit' 'operator' type '(' fixed_parameter ')'
;

operator_body
: block
  | '=>' expression ';'
  | ';'
;

```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

There are three categories of overloadable operators: Unary operators (§14.10.2), binary operators (§14.10.3), and conversion operators (§14.10.4).

The *operator_body* is either a semicolon, a block body (§14.6.1) or an expression body (§14.6.1). A block body consists of a *block*, which specifies the statements to execute when the operator is invoked. The *block* shall conform to the rules for value-returning methods described in §14.6.11. An expression body consists of => followed by an expression and a semicolon, and denotes a single expression to perform when the operator is invoked.

For `extern` operators, the *operator_body* consists simply of a semicolon. For all other operators, the *operator_body* is either a block body or an expression body.

The following rules apply to all operator declarations:

- An operator declaration shall include both a `public` and a `static` modifier.
- The parameter(s) of an operator shall have no modifiers.
- The signature of an operator (§14.10.2, §14.10.3, §14.10.4) shall differ from the signatures of all other operators declared in the same class.

- All types referenced in an operator declaration shall be at least as accessible as the operator itself (§7.5.5).
- It is an error for the same modifier to appear multiple times in an operator declaration.

Each operator category imposes additional restrictions, as described in the following subclauses.

Like other members, operators declared in a base class are inherited by derived classes. Because operator declarations always require the class or struct in which the operator is declared to participate in the signature of the operator, it is not possible for an operator declared in a derived class to hide an operator declared in a base class. Thus, the `new` modifier is never required, and therefore never permitted, in an operator declaration.

Additional information on unary and binary operators can be found in §11.4.

Additional information on conversion operators can be found in §10.5.

14.10.2 Unary operators

The following rules apply to unary operator declarations, where `T` denotes the instance type of the class or struct that contains the operator declaration:

- A unary `+`, `-`, `!`, or `~` operator shall take a single parameter of type `T` or `T?` and can return any type.
- A unary `++` or `--` operator shall take a single parameter of type `T` or `T?` and shall return that same type or a type derived from it.
- A unary `true` or `false` operator shall take a single parameter of type `T` or `T?` and shall return type `bool`.

The signature of a unary operator consists of the operator token (`+`, `-`, `!`, `~`, `++`, `--`, `true`, or `false`) and the type of the single formal parameter. The return type is not part of a unary operator's signature, nor is the name of the formal parameter.

The `true` and `false` unary operators require pair-wise declaration. A compile-time error occurs if a class declares one of these operators without also declaring the other. The `true` and `false` operators are described further in §11.22.

Example: The following example shows an implementation and subsequent usage of `operator++` for an integer vector class:

```
C#
```

```

public class IntVector
{
    public IntVector(int length) {...}
    public int Length { get { ... } } // Read-only
property
    public int this[int index] { get { ... } set { ... } } // Read-
write indexer

    public static IntVector operator++(IntVector iv)
    {
        IntVector temp = new IntVector(iv.Length);
        for (int i = 0; i < iv.Length; i++)
        {
            temp[i] = iv[i] + 1;
        }
        return temp;
    }
}

class Test
{
    static void Main()
    {
        IntVector iv1 = new IntVector(4); // Vector of 4 x 0
        IntVector iv2;
        iv2 = iv1++; // iv2 contains 4 x 0, iv1 contains 4
x 1
        iv2 = ++iv1; // iv2 contains 4 x 2, iv1 contains 4
x 2
    }
}

```

Note how the operator method returns the value produced by adding 1 to the operand, just like the postfix increment and decrement operators (§11.7.14), and the prefix increment and decrement operators (§11.8.6). Unlike in C++, this method should not modify the value of its operand directly as this would violate the standard semantics of the postfix increment operator (§11.7.14).

end example

14.10.3 Binary operators

The following rules apply to binary operator declarations, where `T` denotes the instance type of the class or struct that contains the operator declaration:

- A binary non-shift operator shall take two parameters, at least one of which shall have type `T` or `T?`, and can return any type.

- A binary `<<` or `>>` operator (§11.10) shall take two parameters, the first of which shall have type `T` or `T?` and the second of which shall have type `int` or `int?`, and can return any type. The signature of a binary operator consists of the operator token (`+`, `-`, `*`, `/`, `%`, `&`, `|`, `^`, `<<`, `>>`, `==`, `!=`, `>`, `<`, `>=`, or `<=`) and the types of the two formal parameters. The return type and the names of the formal parameters are not part of a binary operator's signature.

Certain binary operators require pair-wise declaration. For every declaration of either operator of a pair, there shall be a matching declaration of the other operator of the pair. Two operator declarations match if identity conversions exist between their return types and their corresponding parameter types. The following operators require pair-wise declaration:

- operator `==` and operator `!=`
- operator `>` and operator `<`
- operator `>=` and operator `<=`

14.10.4 Conversion operators

A conversion operator declaration introduces a *user-defined conversion* (§10.5), which augments the pre-defined implicit and explicit conversions.

A conversion operator declaration that includes the `implicit` keyword introduces a user-defined implicit conversion. Implicit conversions can occur in a variety of situations, including function member invocations, cast expressions, and assignments. This is described further in §10.2.

A conversion operator declaration that includes the `explicit` keyword introduces a user-defined explicit conversion. Explicit conversions can occur in cast expressions, and are described further in §10.3.

A conversion operator converts from a source type, indicated by the parameter type of the conversion operator, to a target type, indicated by the return type of the conversion operator.

For a given source type `S` and target type `T`, if `S` or `T` are nullable value types, let `S0` and `T0` refer to their underlying types; otherwise, `S0` and `T0` are equal to `S` and `T` respectively. A class or struct is permitted to declare a conversion from a source type `S` to a target type `T` only if all of the following are true:

- `S0` and `T0` are different types.

- Either `S0` or `T0` is the instance type of the class or struct that contains the operator declaration.
- Neither `S0` nor `T0` is an *interface_type*.
- Excluding user-defined conversions, a conversion does not exist from `S` to `T` or from `T` to `S`.

For the purposes of these rules, any type parameters associated with `S` or `T` are considered to be unique types that have no inheritance relationship with other types, and any constraints on those type parameters are ignored.

Example: In the following:

```
C#
class C<T> {...}

class D<T> : C<T>
{
    public static implicit operator C<int>(D<T> value) {...} // Ok
    public static implicit operator C<string>(D<T> value) {...} // Ok
    public static implicit operator C<T>(D<T> value) {...} //
Error
}
```

the first two operator declarations are permitted because `T` and `int` and `string`, respectively are considered unique types with no relationship. However, the third operator is an error because `C<T>` is the base class of `D<T>`.

end example

From the second rule, it follows that a conversion operator shall convert either to or from the class or struct type in which the operator is declared.

Example: It is possible for a class or struct type `C` to define a conversion from `C` to `int` and from `int` to `C`, but not from `int` to `bool`. *end example*

It is not possible to directly redefine a pre-defined conversion. Thus, conversion operators are not allowed to convert from or to `object` because implicit and explicit conversions already exist between `object` and all other types. Likewise, neither the source nor the target types of a conversion can be a base type of the other, since a conversion would then already exist. However, it *is* possible to declare operators on

generic types that, for particular type arguments, specify conversions that already exist as pre-defined conversions.

Example:

```
C#  
  
struct Convertible<T>  
{  
    public static implicit operator Convertible<T>(T value) {...}  
    public static explicit operator T(Convertible<T> value) {...}  
}
```

when type `object` is specified as a type argument for `T`, the second operator declares a conversion that already exists (an implicit, and therefore also an explicit, conversion exists from any type to type `object`).

end example

In cases where a pre-defined conversion exists between two types, any user-defined conversions between those types are ignored. Specifically:

- If a pre-defined implicit conversion (§10.2) exists from type `S` to type `T`, all user-defined conversions (implicit or explicit) from `S` to `T` are ignored.
- If a pre-defined explicit conversion (§10.3) exists from type `S` to type `T`, any user-defined explicit conversions from `S` to `T` are ignored. Furthermore:
 - If either `S` or `T` is an interface type, user-defined implicit conversions from `S` to `T` are ignored.
 - Otherwise, user-defined implicit conversions from `S` to `T` are still considered.

For all types but `object`, the operators declared by the `Convertible<T>` type above do not conflict with pre-defined conversions.

Example:

```
C#  
  
void F(int i, Convertible<int> n)  
{  
    i = n; // Error  
    i = (int)n; // User-defined explicit conversion  
    n = i; // User-defined implicit conversion  
    n = (Convertible<int>)i; // User-defined implicit conversion  
}
```

However, for type `object`, pre-defined conversions hide the user-defined conversions in all cases but one:

```
C#  
  
void F(object o, Convertible<object> n)  
{  
    o = n; // Pre-defined boxing conversion  
    o = (object)n; // Pre-defined boxing conversion  
    n = o; // User-defined implicit conversion  
    n = (Convertible<object>)o; // Pre-defined unboxing conversion  
}
```

end example

User-defined conversions are not allowed to convert from or to *interface_types*. In particular, this restriction ensures that no user-defined transformations occur when converting to an *interface_type*, and that a conversion to an *interface_type* succeeds only if the `object` being converted actually implements the specified *interface_type*.

The signature of a conversion operator consists of the source type and the target type. (This is the only form of member for which the return type participates in the signature.) The implicit or explicit classification of a conversion operator is not part of the operator's signature. Thus, a class or struct cannot declare both an implicit and an explicit conversion operator with the same source and target types.

Note: In general, user-defined implicit conversions should be designed to never throw exceptions and never lose information. If a user-defined conversion can give rise to exceptions (for example, because the source argument is out of range) or loss of information (such as discarding high-order bits), then that conversion should be defined as an explicit conversion. *end note*

Example: In the following code

```
C#  
  
public struct Digit  
{  
    byte value;  
  
    public Digit(byte value)  
    {  
        if (value < 0 || value > 9)  
        {  
            throw new ArgumentException();  
        }  
    }  
}
```

```

        this.value = value;
    }

    public static implicit operator byte(Digit d) => d.value;
    public static explicit operator Digit(byte b) => new Digit(b);
}

```

the conversion from `Digit` to `byte` is implicit because it never throws exceptions or loses information, but the conversion from `byte` to `Digit` is explicit since `Digit` can only represent a subset of the possible values of a `byte`.

end example

14.11 Instance constructors

14.11.1 General

An *instance constructor* is a member that implements the actions required to initialize an instance of a class. Instance constructors are declared using *constructor_declarations*:

ANTLR

```

constructor_declaration
    : attributes? constructor_modifier* constructor_declarator
  constructor_body
  ;

constructor_modifier
    : 'public'
  | 'protected'
  | 'internal'
  | 'private'
  | 'extern'
  | unsafe_modifier // unsafe code support
  ;

constructor_declarator
    : identifier '(' formal_parameter_list? ')' constructor_initializer?
  ;

constructor_initializer
    : ':' 'base' '(' argument_list? ')'
  | ':' 'this' '(' argument_list? ')'
  ;

constructor_body
    : block
  | '=>' expression ';'

```

```
| ';'
;
```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

A *constructor_declaration* may include a set of *attributes* (§21), any one of the permitted kinds of declared accessibility (§14.3.6), and an `extern` (§14.6.8) modifier. A constructor declaration is not permitted to include the same modifier multiple times.

The *identifier* of a *constructor_declarator* shall name the class in which the instance constructor is declared. If any other name is specified, a compile-time error occurs.

The optional *formal_parameter_list* of an instance constructor is subject to the same rules as the *formal_parameter_list* of a method (§14.6). As the `this` modifier for parameters only applies to extension methods (§14.6.10), no parameter in a constructor's *formal_parameter_list* shall contain the `this` modifier. The formal parameter list defines the signature (§7.6) of an instance constructor and governs the process whereby overload resolution (§11.6.4) selects a particular instance constructor in an invocation.

Each of the types referenced in the *formal_parameter_list* of an instance constructor shall be at least as accessible as the constructor itself (§7.5.5).

The optional *constructor_initializer* specifies another instance constructor to invoke before executing the statements given in the *constructor_body* of this instance constructor. This is described further in §14.11.2.

When a constructor declaration includes an `extern` modifier, the constructor is said to be an **external constructor**. Because an external constructor declaration provides no actual implementation, its *constructor_body* consists of a semicolon. For all other constructors, the *constructor_body* consists of either

- a *block*, which specifies the statements to initialize a new instance of the class; or
- an expression body, which consists of `=>` followed by an *expression* and a semicolon, and denotes a single expression to initialize a new instance of the class.

A *constructor_body* that is a *block* or expression body corresponds exactly to the *block* of an instance method with a `void` return type (§14.6.11).

Instance constructors are not inherited. Thus, a class has no instance constructors other than those actually declared in the class, with the exception that if a class contains no instance constructor declarations, a default instance constructor is automatically provided (§14.11.5).

Instance constructors are invoked by *object_creation_expressions* (§11.7.15.2) and through *constructor_initializers*.

14.11.2 Constructor initializers

All instance constructors (except those for class `object`) implicitly include an invocation of another instance constructor immediately before the *constructor_body*. The constructor to implicitly invoke is determined by the *constructor_initializer*:

- An instance constructor initializer of the form `base(argument_list)` (where *argument_list* is optional) causes an instance constructor from the direct base class to be invoked. That constructor is selected using *argument_list* and the overload resolution rules of §11.6.4. The set of candidate instance constructors consists of all the accessible instance constructors of the direct base class. If this set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs.
- An instance constructor initializer of the form `this(argument_list)` (where *argument_list* is optional) invokes another instance constructor from the same class. The constructor is selected using *argument_list* and the overload resolution rules of §11.6.4. The set of candidate instance constructors consists of all instance constructors declared in the class itself. If the resulting set of applicable instance constructors is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs. If an instance constructor declaration invokes itself through a chain of one or more constructor initializers, a compile-time error occurs.

If an instance constructor has no constructor initializer, a constructor initializer of the form `base()` is implicitly provided.

Note: Thus, an instance constructor declaration of the form

```
C#
```

```
C(...) {...}
```

is exactly equivalent to

```
C#
```

```
C(...) : base() {...}
```

end note

The scope of the parameters given by the *formal_parameter_list* of an instance constructor declaration includes the constructor initializer of that declaration. Thus, a constructor initializer is permitted to access the parameters of the constructor.

Example:

```
C#  
  
class A  
{  
    public A(int x, int y) {}  
}  
  
class B: A  
{  
    public B(int x, int y) : base(x + y, x - y) {}  
}
```

end example

An instance constructor initializer cannot access the instance being created. Therefore it is a compile-time error to reference this in an argument expression of the constructor initializer, as it is a compile-time error for an argument expression to reference any instance member through a *simple_name*.

14.11.3 Instance variable initializers

When an instance constructor has no constructor initializer, or it has a constructor initializer of the form `base(...)`, that constructor implicitly performs the initializations specified by the *variable_initializers* of the instance fields declared in its class. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor and before the implicit invocation of the direct base class constructor. The variable initializers are executed in the textual order in which they appear in the class declaration (§14.5.6).

14.11.4 Constructor execution

Variable initializers are transformed into assignment statements, and these assignment statements are executed *before* the invocation of the base class instance constructor. This ordering ensures that all instance fields are initialized by their variable initializers before *any* statements that have access to that instance are executed.

Example: Given the following:

C#

```
class A
{
    public A()
    {
        PrintFields();
    }

    public virtual void PrintFields() {}
}
class B: A
{
    int x = 1;
    int y;

    public B()
    {
        y = -1;
    }

    public override void PrintFields() =>
        Console.WriteLine($"x = {x}, y = {y}");
}
```

when new `B()` is used to create an instance of `B`, the following output is produced:

Console

```
x = 1, y = 0
```

The value of `x` is 1 because the variable initializer is executed before the base class instance constructor is invoked. However, the value of `y` is 0 (the default value of an `int`) because the assignment to `y` is not executed until after the base class constructor returns. It is useful to think of instance variable initializers and constructor initializers as statements that are automatically inserted before the *constructor_body*. The example

C#

```
class A
{
    int x = 1, y = -1, count;

    public A()
    {
        count = 0;
    }
}
```

```

public A(int n)
{
    count = n;
}

class B : A
{
    double sqrt2 = Math.Sqrt(2.0);
    ArrayList items = new ArrayList(100);
    int max;

    public B(): this(100)
    {
        items.Add("default");
    }

    public B(int n) : base(n - 1)
    {
        max = n;
    }
}

```

contains several variable initializers; it also contains constructor initializers of both forms (`base` and `this`). The example corresponds to the code shown below, where each comment indicates an automatically inserted statement (the syntax used for the automatically inserted constructor invocations isn't valid, but merely serves to illustrate the mechanism).

C#

```

class A
{
    int x, y, count;
    public A()
    {
        x = 1; // Variable initializer
        y = -1; // Variable initializer
        object(); // Invoke object() constructor
        count = 0;
    }

    public A(int n)
    {
        x = 1; // Variable initializer
        y = -1; // Variable initializer
        object(); // Invoke object() constructor
        count = n;
    }
}

class B : A

```

```

{
    double sqrt2;
    ArrayList items;
    int max;
    public B() : this(100)
    {
        B(100); // Invoke B(int) constructor
        items.Add("default");
    }

    public B(int n) : base(n - 1)
    {
        sqrt2 = Math.Sqrt(2.0); // Variable initializer
        items = new ArrayList(100); // Variable initializer
        A(n - 1); // Invoke A(int) constructor
        max = n;
    }
}

```

end example

14.11.5 Default constructors

If a class contains no instance constructor declarations, a default instance constructor is automatically provided. That default constructor simply invokes a constructor of the direct base class, as if it had a constructor initializer of the form `base()`. If the class is abstract then the declared accessibility for the default constructor is protected. Otherwise, the declared accessibility for the default constructor is public.

Note: Thus, the default constructor is always of the form

C#

```
protected C(): base() {}
```

or

C#

```
public C(): base() {}
```

where `C` is the name of the class.

end note

If overload resolution is unable to determine a unique best candidate for the base-class constructor initializer then a compile-time error occurs.

Example: In the following code

```
C#  
  
class Message  
{  
    object sender;  
    string text;  
}
```

a default constructor is provided because the class contains no instance constructor declarations. Thus, the example is precisely equivalent to

```
C#  
  
class Message  
{  
    object sender;  
    string text;  
  
    public Message() : base() {}  
}
```

end example

14.12 Static constructors

A **static constructor** is a member that implements the actions required to initialize a closed class. Static constructors are declared using *static_constructor_declarations*:

ANTLR

```
static_constructor_declaration  
    : attributes? static_constructor_modifiers identifier '(' ')' '  
      static_constructor_body  
    ;  
  
static_constructor_modifiers  
    : 'static'  
    | 'static' 'extern' unsafe_modifier?  
    | 'static' unsafe_modifier 'extern'?  
    | 'extern' 'static' unsafe_modifier?  
    | 'extern' unsafe_modifier 'static'  
    | unsafe_modifier 'static' 'extern'?  
    | unsafe_modifier 'extern' 'static'
```

```
;  
  
static_constructor_body  
: block  
| '=>' expression ';' ;  
| ';' ;  
;
```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

A *static_constructor_declaration* may include a set of *attributes* (§21) and an `extern` modifier (§14.6.8).

The *identifier* of a *static_constructor_declaration* shall name the class in which the static constructor is declared. If any other name is specified, a compile-time error occurs.

When a static constructor declaration includes an `extern` modifier, the static constructor is said to be an **external static constructor**. Because an external static constructor declaration provides no actual implementation, its *static_constructor_body* consists of a semicolon. For all other static constructor declarations, the *static_constructor_body* consists of either

- a *block*, which specifies the statements to execute in order to initialize the class; or
- an expression body, which consists of `=>` followed by an *expression* and a semicolon, and denotes a single expression to execute in order to initialize the class.

A *static_constructor_body* that is a *block* or expression body corresponds exactly to the *method_body* of a static method with a `void` return type (§14.6.11).

Static constructors are not inherited, and cannot be called directly.

The static constructor for a closed class executes at most once in a given application domain. The execution of a static constructor is triggered by the first of the following events to occur within an application domain:

- An instance of the class is created.
- Any of the static members of the class are referenced.

If a class contains the `Main` method (§7.1) in which execution begins, the static constructor for that class executes before the `Main` method is called.

To initialize a new closed class type, first a new set of static fields (§14.5.2) for that particular closed type is created. Each of the static fields is initialized to its default value

(§14.5.5). Next, the static field initializers (§14.5.6.2) are executed for those static fields. Finally, the static constructor is executed.

Example: The example

```
C#  
  
class Test  
{  
    static void Main()  
    {  
        A.F();  
        B.F();  
    }  
}  
  
class A  
{  
    static A()  
    {  
        Console.WriteLine("Init A");  
    }  
  
    public static void F()  
    {  
        Console.WriteLine("A.F");  
    }  
}  
  
class B  
{  
    static B()  
    {  
        Console.WriteLine("Init B");  
    }  
  
    public static void F()  
    {  
        Console.WriteLine("B.F");  
    }  
}
```

must produce the output:

```
Console  
  
Init A  
A.F  
Init B  
B.F
```

because the execution of `A`'s static constructor is triggered by the call to `A.F`, and the execution of `B`'s static constructor is triggered by the call to `B.F`.

end example

It is possible to construct circular dependencies that allow static fields with variable initializers to be observed in their default value state.

Example: The example

```
C#  
  
class A  
{  
    public static int X;  
  
    static A()  
    {  
        X = B.Y + 1;  
    }  
}  
  
class B  
{  
    public static int Y = A.X + 1;  
  
    static B() {}  
  
    static void Main()  
    {  
        Console.WriteLine($"X = {A.X}, Y = {B.Y}");  
    }  
}
```

produces the output

```
Console  
  
X = 1, Y = 2
```

To execute the `Main` method, the system first runs the initializer for `B.Y`, prior to class `B`'s static constructor. `Y`'s initializer causes `A`'s static constructor to be run because the value of `A.X` is referenced. The static constructor of `A` in turn proceeds to compute the value of `X`, and in doing so fetches the default value of `Y`, which is zero. `A.X` is thus initialized to 1. The process of running `A`'s static field initializers

and static constructor then completes, returning to the calculation of the initial value of `y`, the result of which becomes 2.

end example

Because the static constructor is executed exactly once for each closed constructed class type, it is a convenient place to enforce run-time checks on the type parameter that cannot be checked at compile-time via constraints (§14.2.5).

Example: The following type uses a static constructor to enforce that the type argument is an enum:

```
C#  
  
class Gen<T> where T : struct  
{  
    static Gen()  
    {  
        if (!typeof(T).IsEnum)  
        {  
            throw new ArgumentException("T must be an enum");  
        }  
    }  
}
```

end example

14.13 Finalizers

Note: In an earlier version of this standard, what is now referred to as a “finalizer” was called a “destructor”. Experience has shown that the term “destructor” caused confusion and often resulted to incorrect expectations, especially to programmers knowing C++. In C++, a destructor is called in a determinate manner, whereas, in C#, a finalizer is not. To get determinate behavior from C#, one should use

`Dispose`. *end note*

A **finalizer** is a member that implements the actions required to finalize an instance of a class. A finalizer is declared using a *finalizer_declaration*:

```
ANTLR  
  
finalizer_declaration  
: attributes? '~' identifier '(' ')' finalizer_body  
| attributes? 'extern' unsafe_modifier? '~' identifier '(' ')'
```

```

finalizer_body
| attributes? unsafe_modifier 'extern'? '~' identifier '(' ')'
finalizer_body
;

finalizer_body
: block
| '=>' expression ';'
| ';'
;

```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

A *finalizer_declaration* may include a set of *attributes* (§21).

The *identifier* of a *finalizer_declarator* shall name the class in which the finalizer is declared. If any other name is specified, a compile-time error occurs.

When a finalizer declaration includes an `extern` modifier, the finalizer is said to be an **external finalizer**. Because an external finalizer declaration provides no actual implementation, its *finalizer_body* consists of a semicolon. For all other finalizers, the *finalizer_body* consists of either

- a *block*, which specifies the statements to execute in order to finalize an instance of the class.
- or an expression body, which consists of `=>` followed by an *expression* and a semicolon, and denotes a single expression to execute in order to finalize an instance of the class.

A *finalizer_body* that is a *block* or expression body corresponds exactly to the *method_body* of an instance method with a `void` return type (§14.6.11).

Finalizers are not inherited. Thus, a class has no finalizers other than the one that may be declared in that class.

Note: Since a finalizer is required to have no parameters, it cannot be overloaded, so a class can have, at most, one finalizer. *end note*

Finalizers are invoked automatically, and cannot be invoked explicitly. An instance becomes eligible for finalization when it is no longer possible for any code to use that instance. Execution of the finalizer for the instance may occur at any time after the instance becomes eligible for finalization (§7.9). When an instance is finalized, the finalizers in that instance's inheritance chain are called, in order, from most derived to least derived. A finalizer may be executed on any thread. For further discussion of the rules that govern when and how a finalizer is executed, see §7.9.

Example: The output of the example

```
C#  
  
class A  
{  
    ~A()  
    {  
        Console.WriteLine("A's finalizer");  
    }  
}  
  
class B : A  
{  
    ~B()  
    {  
        Console.WriteLine("B's finalizer");  
    }  
}  
  
class Test  
{  
    static void Main()  
    {  
        B b = new B();  
        b = null;  
        GC.Collect();  
        GC.WaitForPendingFinalizers();  
    }  
}
```

is

```
Console  
  
B's finalizer  
A's finalizer
```

since finalizers in an inheritance chain are called in order, from most derived to least derived.

end example

Finalizers are implemented by overriding the virtual method `Finalize` on `System.Object`. C# programs are not permitted to override this method or call it (or overrides of it) directly.

Example: For instance, the program

C#

```
class A
{
    override protected void Finalize() {} // Error
    public void F()
    {
        this.Finalize(); // Error
    }
}
```

contains two errors.

end example

The compiler behaves as if this method, and overrides of it, do not exist at all.

Example: Thus, this program:

C#

```
class A
{
    void Finalize() {} // Permitted
}
```

is valid and the method shown hides `System.Object`'s `Finalize` method.

end example

For a discussion of the behavior when an exception is thrown from a finalizer, see [§20.4](#).

14.14 Iterators

14.14.1 General

A function member ([§11.6](#)) implemented using an iterator block ([§12.3](#)) is called an *iterator*.

An iterator block may be used as the body of a function member as long as the return type of the corresponding function member is one of the enumerator interfaces ([§14.14.2](#)) or one of the enumerable interfaces ([§14.14.3](#)). It may occur as a *method_body*, *operator_body* or *accessor_body*, whereas events, instance constructors, static constructors and finalizers may not be implemented as iterators.

When a function member is implemented using an iterator block, it is a compile-time error for the formal parameter list of the function member to specify any `ref` or `out` parameters.

14.14.2 Enumerator interfaces

The *enumerator interfaces* are the non-generic interface `System.Collections.IEnumerator` and all instantiations of the generic interface `System.Collections.Generic.IEnumerator<T>`. For the sake of brevity, in this subclause and its siblings these interfaces are referenced as `IEnumerator` and `IEnumerator<T>`, respectively.

14.14.3 Enumerable interfaces

The *enumerable interfaces* are the non-generic interface `System.Collections.IEnumerable` and all instantiations of the generic interface `System.Collections.Generic.IEnumerable<T>`. For the sake of brevity, in this subclause and its siblings these interfaces are referenced as `IEnumerable` and `IEnumerable<T>`, respectively.

14.14.4 Yield type

An iterator produces a sequence of values, all of the same type. This type is called the *yield type* of the iterator.

- The yield type of an iterator that returns `IEnumerator` or `IEnumerable` is `object`.
- The yield type of an iterator that returns `IEnumerator<T>` or `IEnumerable<T>` is `T`.

14.14.5 Enumerator objects

14.14.5.1 General

When a function member returning an enumerator interface type is implemented using an iterator block, invoking the function member does not immediately execute the code in the iterator block. Instead, an *enumerator object* is created and returned. This object encapsulates the code specified in the iterator block, and execution of the code in the iterator block occurs when the enumerator object's `MoveNext` method is invoked. An enumerator object has the following characteristics:

- It implements `IEnumerator` and `IEnumerator<T>`, where `T` is the yield type of the iterator.
- It implements `System.IDisposable`.
- It is initialized with a copy of the argument values (if any) and instance value passed to the function member.
- It has four potential states, **before**, **running**, **suspended**, and **after**, and is initially in the **before** state.

An enumerator object is typically an instance of a compiler-generated enumerator class that encapsulates the code in the iterator block and implements the enumerator interfaces, but other methods of implementation are possible. If an enumerator class is generated by the compiler, that class will be nested, directly or indirectly, in the class containing the function member, it will have private accessibility, and it will have a name reserved for compiler use (§6.4.3).

An enumerator object may implement more interfaces than those specified above.

The following subclauses describe the required behavior of the `MoveNext`, `Current`, and `Dispose` members of the `IEnumerator` and `IEnumerator<T>` interface implementations provided by an enumerator object.

Enumerator objects do not support the `IEnumerator.Reset` method. Invoking this method causes a `System.NotSupportedException` to be thrown.

14.14.5.2 The `MoveNext` method

The `MoveNext` method of an enumerator object encapsulates the code of an iterator block. Invoking the `MoveNext` method executes code in the iterator block and sets the `Current` property of the enumerator object as appropriate. The precise action performed by `MoveNext` depends on the state of the enumerator object when `MoveNext` is invoked:

- If the state of the enumerator object is **before**, invoking `MoveNext`:
 - Changes the state to **running**.
 - Initializes the parameters (including `this`) of the iterator block to the argument values and instance value saved when the enumerator object was initialized.
 - Executes the iterator block from the beginning until execution is interrupted (as described below).
- If the state of the enumerator object is **running**, the result of invoking `MoveNext` is unspecified.
- If the state of the enumerator object is **suspended**, invoking `MoveNext`:

- Changes the state to **running**.
- Restores the values of all local variables and parameters (including `this`) to the values saved when execution of the iterator block was last suspended.

Note: The contents of any objects referenced by these variables may have changed since the previous call to `MoveNext`. *end note*

- Resumes execution of the iterator block immediately following the `yield return` statement that caused the suspension of execution and continues until execution is interrupted (as described below).
- If the state of the enumerator object is **after**, invoking `MoveNext` returns false.

When `MoveNext` executes the iterator block, execution can be interrupted in four ways: By a `yield return` statement, by a `yield break` statement, by encountering the end of the iterator block, and by an exception being thrown and propagated out of the iterator block.

- When a `yield return` statement is encountered (§9.4.4.20):
 - The expression given in the statement is evaluated, implicitly converted to the `yield` type, and assigned to the `Current` property of the enumerator object.
 - Execution of the iterator body is suspended. The values of all local variables and parameters (including `this`) are saved, as is the location of this `yield return` statement. If the `yield return` statement is within one or more `try` blocks, the associated `finally` blocks are *not* executed at this time.
 - The state of the enumerator object is changed to **suspended**.
 - The `MoveNext` method returns `true` to its caller, indicating that the iteration successfully advanced to the next value.
- When a `yield break` statement is encountered (§9.4.4.20):
 - If the `yield break` statement is within one or more `try` blocks, the associated `finally` blocks are executed.
 - The state of the enumerator object is changed to **after**.
 - The `MoveNext` method returns `false` to its caller, indicating that the iteration is complete.
- When the end of the iterator body is encountered:
 - The state of the enumerator object is changed to **after**.
 - The `MoveNext` method returns `false` to its caller, indicating that the iteration is complete.
- When an exception is thrown and propagated out of the iterator block:
 - Appropriate `finally` blocks in the iterator body will have been executed by the exception propagation.

- The state of the enumerator object is changed to **after**.
- The exception propagation continues to the caller of the `MoveNext` method.

14.14.5.3 The Current property

An enumerator object's `Current` property is affected by `yield return` statements in the iterator block.

When an enumerator object is in the **suspended** state, the value of `Current` is the value set by the previous call to `MoveNext`. When an enumerator object is in the **before**, **running**, or **after** states, the result of accessing `Current` is unspecified.

For an iterator with a yield type other than `object`, the result of accessing `Current` through the enumerator object's `IEnumerable` implementation corresponds to accessing `Current` through the enumerator object's `IEnumerator<T>` implementation and casting the result to `object`.

14.14.5.4 The Dispose method

The `Dispose` method is used to clean up the iteration by bringing the enumerator object to the **after** state.

- If the state of the enumerator object is **before**, invoking `Dispose` changes the state to **after**.
- If the state of the enumerator object is **running**, the result of invoking `Dispose` is unspecified.
- If the state of the enumerator object is **suspended**, invoking `Dispose`:
 - Changes the state to **running**.
 - Executes any finally blocks as if the last executed `yield return` statement were a `yield break` statement. If this causes an exception to be thrown and propagated out of the iterator body, the state of the enumerator object is set to **after** and the exception is propagated to the caller of the `Dispose` method.
 - Changes the state to **after**.
- If the state of the enumerator object is **after**, invoking `Dispose` has no effect.

14.14.6 Enumerable objects

14.14.6.1 General

When a function member returning an enumerable interface type is implemented using an iterator block, invoking the function member does not immediately execute the code in the iterator block. Instead, an **enumerable object** is created and returned. The enumerable object's `GetEnumerator` method returns an enumerator object that encapsulates the code specified in the iterator block, and execution of the code in the iterator block occurs when the enumerator object's `MoveNext` method is invoked. An enumerable object has the following characteristics:

- It implements `IEnumerable` and `IEnumerable<T>`, where `T` is the yield type of the iterator.
- It is initialized with a copy of the argument values (if any) and instance value passed to the function member.

An enumerable object is typically an instance of a compiler-generated enumerable class that encapsulates the code in the iterator block and implements the enumerable interfaces, but other methods of implementation are possible. If an enumerable class is generated by the compiler, that class will be nested, directly or indirectly, in the class containing the function member, it will have private accessibility, and it will have a name reserved for compiler use ([§6.4.3](#)).

An enumerable object may implement more interfaces than those specified above.

Note: For example, an enumerable object may also implement `IEnumerator` and `IEnumerator<T>`, enabling it to serve as both an enumerable and an enumerator. Typically, such an implementation would return its own instance (to save allocations) from the first call to `GetEnumerator`. Subsequent invocations of `GetEnumerator`, if any, would return a new class instance, typically of the same class, so that calls to different enumerator instances will not affect each other. It cannot return the same instance even if the previous enumerator has already enumerated past the end of the sequence, since all future calls to an exhausted enumerator must throw exceptions. *end note*

14.14.6.2 The `GetEnumerator` method

An enumerable object provides an implementation of the `GetEnumerator` methods of the `IEnumerable` and `IEnumerable<T>` interfaces. The two `GetEnumerator` methods share a common implementation that acquires and returns an available enumerator object. The enumerator object is initialized with the argument values and instance value saved when the enumerable object was initialized, but otherwise the enumerator object functions as described in [§14.14.5](#).

14.15 Async Functions

14.15.1 General

A method (§14.6) or anonymous function (§11.17) with the `async` modifier is called an **async function**. In general, the term **async** is used to describe any kind of function that has the `async` modifier.

It is a compile-time error for the formal parameter list of an async function to specify any `ref` or `out` parameters.

The *return_type* of an async method shall be either `void` or a **task type**. The task types are `System.Threading.Tasks.Task` and types constructed from `System.Threading.Tasks.Task<T>`. For the sake of brevity, in this clause these types are referenced as `Task` and `Task<T>`, respectively. An async method returning a task type is said to be **task-returning**.

The exact definition of the task types is implementation-defined, but from the language's point of view, a task type is in one of the states *incomplete*, *succeeded* or *faulted*. A *faulted* task records a pertinent exception. A *succeeded* `Task<T>` records a result of type `T`. Task types are awaitable, and tasks can therefore be the operands of await expressions (§11.8.8).

An async function has the ability to suspend evaluation by means of await expressions (§11.8.8) in its body. Evaluation may later be resumed at the point of the suspending await expression by means of a **resumption delegate**. The resumption delegate is of type `System.Action`, and when it is invoked, evaluation of the async function invocation will resume from the await expression where it left off. The **current caller** of an async function invocation is the original caller if the function invocation has never been suspended or the most recent caller of the resumption delegate otherwise.

14.15.2 Evaluation of a task-returning async function

Invocation of a task-returning async function causes an instance of the returned task type to be generated. This is called the **return task** of the async function. The task is initially in an *incomplete* state.

The async function body is then evaluated until it is either suspended (by reaching an await expression) or terminates, at which point control is returned to the caller, along with the return task.

When the body of the async function terminates, the return task is moved out of the incomplete state:

- If the function body terminates as the result of reaching a return statement or the end of the body, any result value is recorded in the return task, which is put into a *succeeded* state.
- If the function body terminates as the result of an uncaught exception ([§12.10.6](#)) the exception is recorded in the return task which is put into a *faulted* state.

14.15.3 Evaluation of a void-returning async function

If the return type of the async function is `void`, evaluation differs from the above in the following way: Because no task is returned, the function instead communicates completion and exceptions to the current thread's ***synchronization context***. The exact definition of synchronization context is implementation-dependent, but is a representation of "where" the current thread is running. The synchronization context is notified when evaluation of a `void`-returning async function commences, completes successfully, or causes an uncaught exception to be thrown.

This allows the context to keep track of how many `void`-returning async functions are running under it, and to decide how to propagate exceptions coming out of them.

15 Structs

Article • 2023-01-13 • 15 minutes to read

15.1 General

Structs are similar to classes in that they represent data structures that can contain data members and function members. However, unlike classes, structs are value types and do not require heap allocation. A variable of a `struct` type directly contains the data of the `struct`, whereas a variable of a class type contains a reference to the data, the latter known as an object.

Note: Structs are particularly useful for small data structures that have value semantics. Complex numbers, points in a coordinate system, or key-value pairs in a dictionary are all good examples of structs. Key to these data structures is that they have few data members, that they do not require use of inheritance or reference semantics, rather they can be conveniently implemented using value semantics where assignment copies the value instead of the reference. *end note*

As described in §8.3.5, the simple types provided by C#, such as `int`, `double`, and `bool`, are, in fact, all struct types.

15.2 Struct declarations

15.2.1 General

A *struct_declaration* is a *type_declaration* (§13.7) that declares a new struct:

ANTLR

```
struct_declaration
: attributes? struct_modifier* 'partial'? 'struct'
  identifier type_parameter_list? struct_interfaces?
  type_parameter_constraints_clause* struct_body ';'
;
```

A *struct_declaration* consists of an optional set of *attributes* (§21), followed by an optional set of *struct_modifiers* (§15.2.2), followed by an optional partial modifier (§14.2.7), followed by the keyword `struct` and an *identifier* that names the struct, followed by an optional *type_parameter_list* specification (§14.2.3), followed by an

optional *struct_interfaces* specification (§15.2.4), followed by an optional *type_parameter_constraints-clauses* specification (§14.2.5), followed by a *struct_body* (§15.2.5), optionally followed by a semicolon.

A struct declaration shall not supply a *type_parameter_constraints-clauses* unless it also supplies a *type_parameter_list*.

A struct declaration that supplies a *type_parameter_list* is a generic struct declaration. Additionally, any struct nested inside a generic class declaration or a generic struct declaration is itself a generic struct declaration, since type arguments for the containing type shall be supplied to create a constructed type (§8.4).

15.2.2 Struct modifiers

A *struct_declaration* may optionally include a sequence of *struct_modifiers*:

ANTLR

```
struct_modifier
  : 'new'
  | 'public'
  | 'protected'
  | 'internal'
  | 'private'
  | 'readonly'
  | unsafe_modifier // unsafe code support
  ;
```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

It is a compile-time error for the same modifier to appear multiple times in a struct declaration.

Except for `readonly`, the modifiers of a struct declaration have the same meaning as those of a class declaration (§14.2.2).

The `readonly` modifier indicates that the *struct_declaration* declares a type whose instances are immutable.

A readonly struct has the following constraints:

- Each of its instance fields shall also be declared `readonly`.
- None of its instance properties shall have a *set_accessor_declaration* (§14.7.3).
- It shall not declare any field-like events (§14.8.2).

When an instance of a readonly struct is passed to a method, its `this` is treated like an `in` argument/parameter, which disallows write access to any instance fields (except by constructors).

15.2.3 Partial modifier

The `partial` modifier indicates that this *struct_declaration* is a partial type declaration. Multiple partial struct declarations with the same name within an enclosing namespace or type declaration combine to form one struct declaration, following the rules specified in §14.2.7.

15.2.4 Struct interfaces

A struct declaration may include a *struct_interfaces* specification, in which case the struct is said to directly implement the given interface types. For a constructed struct type, including a nested type declared within a generic type declaration (§14.3.9.7), each implemented interface type is obtained by substituting, for each *type_parameter* in the given interface, the corresponding *type_argument* of the constructed type.

ANTLR

```
struct_interfaces
    : ':' interface_type_list
    ;
```

The handling of interfaces on multiple parts of a partial struct declaration (§14.2.7) are discussed further in §14.2.4.3.

Interface implementations are discussed further in §17.6.

15.2.5 Struct body

The *struct_body* of a struct defines the members of the struct.

ANTLR

```
struct_body
    : '{' struct_member_declaration* '}'
    ;
```

15.3 Struct members

The members of a struct consist of the members introduced by its *struct_member_declarations* and the members inherited from the type `System.ValueType`.

ANTLR

```
struct_member_declaration
    : constant_declaration
    | field_declaration
    | method_declaration
    | property_declaration
    | event_declaration
    | indexer_declaration
    | operator_declaration
    | constructor_declaration
    | static_constructor_declaration
    | type_declaration
    | fixed_size_buffer_declaration // unsafe code support
    ;
```

fixed_size_buffer_declaration (§22.8.2) is only available in unsafe code (§22).

Note: All kinds of *class_member_declarations* except *finalizer_declaration* are also *struct_member_declarations*. *end note*

Except for the differences noted in §15.4, the descriptions of class members provided in §14.3 through §14.12 apply to struct members as well.

15.4 Class and struct differences

15.4.1 General

Structs differ from classes in several important ways:

- Structs are value types (§15.4.2).
- All struct types implicitly inherit from the class `System.ValueType` (§15.4.3).
- Assignment to a variable of a struct type creates a *copy* of the value being assigned (§15.4.4).
- The default value of a struct is the value produced by setting all fields to their default value (§15.4.5).
- Boxing and unboxing operations are used to convert between a struct type and certain reference types (§15.4.6).
- The meaning of `this` is different within struct members (§15.4.7).

- Instance field declarations for a struct are not permitted to include variable initializers (§15.4.8).
- A struct is not permitted to declare a parameterless instance constructor (§15.4.9).
- A struct is not permitted to declare a finalizer.

15.4.2 Value semantics

Structs are value types (§8.3) and are said to have value semantics. Classes, on the other hand, are reference types (§8.2) and are said to have reference semantics.

A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to an object that contains the data. When a struct `B` contains an instance field of type `A` and `A` is a struct type, it is a compile-time error for `A` to depend on `B` or a type constructed from `B`. A struct `X` *directly depends on* a struct `Y` if `X` contains an instance field of type `Y`. Given this definition, the complete set of structs upon which a struct depends is the transitive closure of the *directly depends on* relationship.

Example:

```
C#  
  
struct Node  
{  
    int data;  
    Node next; // error, Node directly depends on itself  
}
```

is an error because `Node` contains an instance field of its own type. Another example

```
C#  
  
struct A { B b; }  
struct B { C c; }  
struct C { A a; }
```

is an error because each of the types `A`, `B`, and `C` depend on each other.

end example

With classes, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With structs, the variables each have their own copy of the data (except in the

case of `ref` and `out` parameter variables), and it is not possible for operations on one to affect the other. Furthermore, except when explicitly nullable (§8.3.11), it is not possible for values of a struct type to be `null`.

Note: If a struct contains a field of reference type then the contents of the object referenced can be altered by other operations. However the value of the field itself, i.e., which object it references, cannot be changed through a mutation of a different struct value. *end note*

Example: Given the following

```
C#  
  
struct Point  
{  
    public int x, y;  
  
    public Point(int x, int y)  
    {  
        this.x = x;  
        this.y = y;  
    }  
}  
  
class A  
{  
    static void Main()  
    {  
        Point a = new Point(10, 10);  
        Point b = a;  
        a.x = 100;  
        Console.WriteLine(b.x);  
    }  
}
```

the output is `10`. The assignment of `a` to `b` creates a copy of the value, and `b` is thus unaffected by the assignment to `a.x`. Had `Point` instead been declared as a class, the output would be `100` because `a` and `b` would reference the same object.

end example

15.4.3 Inheritance

All struct types implicitly inherit from the class `System.ValueType`, which, in turn, inherits from class `object`. A struct declaration may specify a list of implemented interfaces, but it is not possible for a struct declaration to specify a base class.

Struct types are never abstract and are always implicitly sealed. The `abstract` and `sealed` modifiers are therefore not permitted in a struct declaration.

Since inheritance isn't supported for structs, the declared accessibility of a struct member cannot be `protected`, `private protected`, or `protected internal`.

Function members in a struct cannot be abstract or virtual, and the `override` modifier is allowed only to override methods inherited from `System.ValueType`.

15.4.4 Assignment

Assignment to a variable of a struct type creates a *copy* of the value being assigned. This differs from assignment to a variable of a class type, which copies the reference but not the object identified by the reference.

Similar to an assignment, when a struct is passed as a value parameter or returned as the result of a function member, a copy of the struct is created. A struct may be passed by reference to a function member using a `ref` or `out` parameter.

When a property or indexer of a struct is the target of an assignment, the instance expression associated with the property or indexer access shall be classified as a variable. If the `instance` expression is classified as a value, a compile-time error occurs. This is described in further detail in [§11.19.2](#).

15.4.5 Default values

As described in [§9.3](#), several kinds of variables are automatically initialized to their default value when they are created. For variables of class types and other reference types, this default value is `null`. However, since structs are value types that cannot be `null`, the default value of a struct is the value produced by setting all value type fields to their default value and all reference type fields to `null`.

Example: Referring to the `Point` struct declared above, the example

```
C#  
  
Point[] a = new Point[100];
```

initializes each `Point` in the array to the value produced by setting the `x` and `y` fields to zero.

end example

The default value of a struct corresponds to the value returned by the default constructor of the struct (§8.3.3). Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor, which always returns the value that results from setting all fields to their default values.

Note: Structs should be designed to consider the default initialization state a valid state. In the example

```
C#  
  
struct KeyValuePair  
{  
    string key;  
    string value;  
  
    public KeyValuePair(string key, string value)  
    {  
        if (key == null || value == null)  
        {  
            throw new ArgumentException();  
        }  
  
        this.key = key;  
        this.value = value;  
    }  
}
```

the user-defined instance constructor protects against `null` values only where it is explicitly called. In cases where a `KeyValuePair` variable is subject to default value initialization, the `key` and `value` fields will be `null`, and the struct should be prepared to handle this state.

end note

15.4.6 Boxing and unboxing

A value of a class type can be converted to type `object` or to an interface type that is implemented by the class simply by treating the reference as another type at compile-time. Likewise, a value of type `object` or a value of an interface type can be converted back to a class type without changing the reference (but, of course, a run-time type check is required in this case).

Since structs are not reference types, these operations are implemented differently for struct types. When a value of a struct type is converted to certain reference types (as

defined in §10.2.9), a boxing operation takes place. Likewise, when a value of certain reference types (as defined in §10.3.6) is converted back to a struct type, an unboxing operation takes place. A key difference from the same operations on class types is that boxing and unboxing *copies* the struct value either into or out of the boxed instance.

Note: Thus, following a boxing or unboxing operation, changes made to the unboxed `struct` are not reflected in the boxed `struct`. *end note*

For further details on boxing and unboxing, see §10.2.9 and §10.3.6.

15.4.7 Meaning of this

The meaning of `this` in a struct differs from the meaning of `this` in a class, as described in §11.7.12. When a struct type overrides a virtual method inherited from `System.ValueType` (such as `Equals`, `GetHashCode`, or `ToString`), invocation of the virtual method through an instance of the struct type does not cause boxing to occur. This is true even when the struct is used as a type parameter and the invocation occurs through an instance of the type parameter type.

Example:

```
C#  
  
struct Counter  
{  
    int value;  
    public override string ToString()  
    {  
        value++;  
        return value.ToString();  
    }  
}  
  
class Program  
{  
    static void Test<T>() where T : new()  
    {  
        T x = new T();  
        Console.WriteLine(x.ToString());  
        Console.WriteLine(x.ToString());  
        Console.WriteLine(x.ToString());  
    }  
  
    static void Main() => Test<Counter>();  
}
```

The output of the program is:

Console

```
1
2
3
```

Although it is bad style for `ToString` to have side effects, the example demonstrates that no boxing occurred for the three invocations of `x.ToString()`.

end example

Similarly, boxing never implicitly occurs when accessing a member on a constrained type parameter when the member is implemented within the value type. For example, suppose an interface `ICounter` contains a method `Increment`, which can be used to modify a value. If `ICounter` is used as a constraint, the implementation of the `Increment` method is called with a reference to the variable that `Increment` was called on, never a boxed copy.

Example:

C#

```
interface ICounter
{
    void Increment();
}

struct Counter : ICounter
{
    int value;

    public override string ToString() => value.ToString();

    void ICounter.Increment() => value++;
}

class Program
{
    static void Test<T>() where T : ICounter, new()
    {
        T x = new T();
        Console.WriteLine(x);
        x.Increment();           // Modify x
        Console.WriteLine(x);
        ((ICounter)x).Increment(); // Modify boxed copy of x
        Console.WriteLine(x);
    }
}
```

```
    }  
  
    static void Main() => Test<Counter>();  
}
```

The first call to `Increment` modifies the value in the variable `x`. This is not equivalent to the second call to `Increment`, which modifies the value in a boxed copy of `x`.

Thus, the output of the program is:

Console

```
0  
1  
1
```

end example

15.4.8 Field initializers

As described in §15.4.5, the default value of a struct consists of the value that results from setting all value type fields to their default value and all reference type fields to `null`. For this reason, a struct does not permit instance field declarations to include variable initializers. This restriction applies only to instance fields. Static fields of a struct are permitted to include variable initializers.

Example: The following

```
C#  
  
struct Point  
{  
    public int x = 1; // Error, initializer not permitted  
    public int y = 1; // Error, initializer not permitted  
}
```

is in error because the instance field declarations include variable initializers.

end example

15.4.9 Constructors

Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor, which always returns the value that results from setting all value type fields to their default value and

all reference type fields to `null` (§8.3.3). A struct can declare instance constructors having parameters.

Example: Given the following

```
C#  
  
struct Point  
{  
    int x, y;  
  
    public Point(int x, int y)  
    {  
        this.x = x;  
        this.y = y;  
    }  
}  
  
class A  
{  
    static void Main()  
    {  
        Point p1 = new Point();  
        Point p2 = new Point(0, 0);  
    }  
}
```

the statements both create a `Point` with `x` and `y` initialized to zero.

end example

A struct instance constructor is not permitted to include a constructor initializer of the form `base(argument_list)`, where `argument_list` is optional.

The `this` parameter of a struct instance constructor corresponds to an `out` parameter of the struct type. As such, `this` shall be definitely assigned (§9.4) at every location where the constructor returns. Similarly, it cannot be read (even implicitly) in the constructor body before being definitely assigned.

If the struct instance constructor specifies a constructor initializer, that initializer is considered a definite assignment to `this` that occurs prior to the body of the constructor. Therefore, the body itself has no initialization requirements.

Example: Consider the instance constructor implementation below:

```
C#
```

```

struct Point
{
    int x, y;

    public int X
    {
        set { x = value; }
    }

    public int Y
    {
        set { y = value; }
    }

    public Point(int x, int y)
    {
        X = x; // error, this is not yet definitely assigned
        Y = y; // error, this is not yet definitely assigned
    }
}

```

No instance function member (including the set accessors for the properties `X` and `Y`) can be called until all fields of the struct being constructed have been definitely assigned. Note, however, that if `Point` were a class instead of a struct, the instance constructor implementation would be permitted. There is one exception to this, and that involves automatically implemented properties (§14.7.4). The definite assignment rules (§11.19.2) specifically exempt assignment to an auto-property of a struct type within an instance constructor of that struct type: such an assignment is considered a definite assignment of the hidden backing field of the auto-property. Thus, the following is allowed:

```

C#

struct Point
{
    public int X { get; set; }
    public int Y { get; set; }

    public Point(int x, int y)
    {
        X = x; // allowed, definitely assigns backing field
        Y = y; // allowed, definitely assigns backing field
    }
}

```

end example]

15.4.10 Static constructors

Static constructors for structs follow most of the same rules as for classes. The execution of a static constructor for a struct type is triggered by the first of the following events to occur within an application domain:

- A static member of the struct type is referenced.
- An explicitly declared constructor of the struct type is called.

Note: The creation of default values (§15.4.5) of struct types does not trigger the static constructor. (An example of this is the initial value of elements in an array.)
end note

15.4.11 Automatically implemented properties

Automatically implemented properties (§14.7.4) use hidden backing fields, which are only accessible to the property accessors.

Note: This access restriction means that constructors in structs containing automatically implemented properties often need an explicit constructor initializer where they would not otherwise need one, to satisfy the requirement of all fields being definitely assigned before any function member is invoked or the constructor returns. *end note*

16 Arrays

Article • 2023-01-12 • 11 minutes to read

16.1 General

An array is a data structure that contains a number of variables that are accessed through computed indices. The variables contained in an array, also called the *elements* of the array, are all of the same type, and this type is called the *element type* of the array.

An array has a rank that determines the number of indices associated with each array element. The rank of an array is also referred to as the dimensions of the array. An array with a rank of one is called a *single-dimensional array*. An array with a rank greater than one is called a *multi-dimensional array*. Specific sized multi-dimensional arrays are often referred to as two-dimensional arrays, three-dimensional arrays, and so on. Each dimension of an array has an associated length that is an integral number greater than or equal to zero. The dimension lengths are not part of the type of the array, but rather are established when an instance of the array type is created at run-time. The length of a dimension determines the valid range of indices for that dimension: For a dimension of length N , indices can range from 0 to $N - 1$ inclusive. The total number of elements in an array is the product of the lengths of each dimension in the array. If one or more of the dimensions of an array have a length of zero, the array is said to be empty.

The element type of an array can itself be an array type (§16.2.1). Such arrays of arrays are distinct from multi-dimensional arrays and can be used to represent “jagged arrays”.

Example:

```
C#  
  
int[][] pascals =  
{  
    new int[] {1},  
    new int[] {1, 1},  
    new int[] {1, 2, 1},  
    new int[] {1, 3, 3, 1}  
};
```

end example

Every array type is a reference type (§8.2). The element type of an array can be any type, including value types and array types.

16.2 Array types

16.2.1 General

The grammar productions for array types are provided in §8.2.1.

An array type is written as a *non_array_type* followed by one or more *rank_specifiers*.

A *non_array_type* is any *type* that is not itself an *array_type*.

The rank of an array type is given by the leftmost *rank_specifier* in the *array_type*: A *rank_specifier* indicates that the array is an array with a rank of one plus the number of “,” tokens in the *rank_specifier*.

The element type of an array type is the type that results from deleting the leftmost *rank_specifier*:

- An array type of the form `T[R]` is an array with rank `R` and a non-array element type `T`.
- An array type of the form `T[R][R1]. . . [Rx]` is an array with rank `R` and an element type `T[R1]. . . [Rx]`.

In effect, the *rank_specifiers* are read from left to right *before* the final non-array element type.

Example: The type in `T[][,,][,]` is a single-dimensional array of three-dimensional arrays of two-dimensional arrays of `int`. *end example*

At run-time, a value of an array type can be `null` or a reference to an instance of that array type.

Note: Following the rules of §16.6, the value may also be a reference to a covariant array type. *end note*

16.2.2 The System.Array type

The type `System.Array` is the abstract base type of all array types. An implicit reference conversion (§10.2.8) exists from any array type to `System.Array` and to any interface type

implemented by `System.Array`. An explicit reference conversion (§10.3.5) exists from `System.Array` and any interface type implemented by `System.Array` to any array type. `System.Array` is not itself an *array_type*. Rather, it is a *class_type* from which all *array_types* are derived.

At run-time, a value of type `System.Array` can be `null` or a reference to an instance of any array type.

16.2.3 Arrays and the generic collection interfaces

A single-dimensional array `T[]` implements the interface `System.Collections.Generic.ICollection<T>` (`ICollection<T>` for short) and its base interfaces. Accordingly, there is an implicit conversion from `T[]` to `ICollection<T>` and its base interfaces. In addition, if there is an implicit reference conversion from `S` to `T` then `S[]` implements `ICollection<T>` and there is an implicit reference conversion from `S[]` to `ICollection<T>` and its base interfaces (§10.2.8). If there is an explicit reference conversion from `S` to `T` then there is an explicit reference conversion from `S[]` to `ICollection<T>` and its base interfaces (§10.3.5).

Similarly, a single-dimensional array `T[]` also implements the interface `System.Collections.Generic.IReadOnlyList<T>` (`IReadOnlyList<T>` for short) and its base interfaces. Accordingly, there is an implicit conversion from `T[]` to `IReadOnlyList<T>` and its base interfaces. In addition, if there is an implicit reference conversion from `S` to `T` then `S[]` implements `IReadOnlyList<T>` and there is an implicit reference conversion from `S[]` to `IReadOnlyList<T>` and its base interfaces (§10.2.8). If there is an explicit reference conversion from `S` to `T` then there is an explicit reference conversion from `S[]` to `IReadOnlyList<T>` and its base interfaces (§10.3.5).

Example: For example:

```
C#  
  
class Test  
{  
    static void Main()  
    {  
        string[] sa = new string[5];  
        object[] oa1 = new object[5];  
        object[] oa2 = sa;  
  
        IList<string> lst1 = sa; // Ok  
        IList<string> lst2 = oa1; // Error, cast needed  
        IList<object> lst3 = sa; // Ok  
        IList<object> lst4 = oa1; // Ok  
    }  
}
```

```

IList<string> lst5 = (IList<string>)oa1; // Exception
IList<string> lst6 = (IList<string>)oa2; // Ok

IReadOnlyList<string> lst7 = sa;           // Ok
IReadOnlyList<string> lst8 = oa1;         // Error, cast needed
IReadOnlyList<object> lst9 = sa;         // Ok
IReadOnlyList<object> lst10 = oa1;       // Ok
IReadOnlyList<string> lst11 = (IReadOnlyList<string>)oa1; //
Exception
    IReadOnlyList<string> lst12 = (IReadOnlyList<string>)oa2; // Ok
}
}

```

The assignment `lst2 = oa1` generates a compile-time error since the conversion from `object[]` to `IList<string>` is an explicit conversion, not implicit. The cast `(IList<string>)oa1` will cause an exception to be thrown at run-time since `oa1` references an `object[]` and not a `string[]`. However the cast `(IList<string>)oa2` will not cause an exception to be thrown since `oa2` references a `string[]`.

end example

Whenever there is an implicit or explicit reference conversion from `S[]` to `IList<T>`, there is also an explicit reference conversion from `IList<T>` and its base interfaces to `S[]` (§10.3.5).

When an array type `S[]` implements `IList<T>`, some of the members of the implemented interface may throw exceptions. The precise behavior of the implementation of the interface is beyond the scope of this specification.

16.3 Array creation

Array instances are created by *array_creation_expressions* (§11.7.15.5) or by field or local variable declarations that include an *array_initializer* (§16.7). Array instances can also be created implicitly as part of evaluating an argument list involving a parameter array (§14.6.2.5).

When an array instance is created, the rank and length of each dimension are established and then remain constant for the entire lifetime of the instance. In other words, it is not possible to change the rank of an existing array instance, nor is it possible to resize its dimensions.

An array instance is always of an array type. The `System.Array` type is an abstract type that cannot be instantiated.

Elements of arrays created by *array_creation_expressions* are always initialized to their default value (§9.3).

16.4 Array element access

Array elements are accessed using *element_access* expressions (§11.7.10.2) of the form `A[I1, I2, ..., Ix]`, where `A` is an expression of an array type and each `Ie` is an expression of type `int`, `uint`, `long`, `ulong`, or can be implicitly converted to one or more of these types. The result of an array element access is a variable, namely the array element selected by the indices.

The elements of an array can be enumerated using a `foreach` statement (§12.9.5).

16.5 Array members

Every array type inherits the members declared by the `System.Array` type.

16.6 Array covariance

For any two *reference_types* `A` and `B`, if an implicit reference conversion (§10.2.8) or explicit reference conversion (§10.3.5) exists from `A` to `B`, then the same reference conversion also exists from the array type `A[R]` to the array type `B[R]`, where `R` is any given *rank_specifier* (but the same for both array types). This relationship is known as **array covariance**. Array covariance, in particular, means that a value of an array type `A[R]` might actually be a reference to an instance of an array type `B[R]`, provided an implicit reference conversion exists from `B` to `A`.

Because of array covariance, assignments to elements of reference type arrays include a run-time check which ensures that the value being assigned to the array element is actually of a permitted type (§11.19.2).

Example:

```
C#  
  
class Test  
{  
    static void Fill(object[] array, int index, int count, object value)  
    {  
        for (int i = index; i < index + count; i++)  
        {  
            array[i] = value;  
        }  
    }  
}
```

```

    }
}

static void Main()
{
    string[] strings = new string[100];
    Fill(strings, 0, 100, "Undefined");
    Fill(strings, 0, 10, null);
    Fill(strings, 90, 10, 0);
}
}

```

The assignment to `array[i]` in the `Fill` method implicitly includes a run-time check, which ensures that `value` is either a `null` reference or a reference to an object of a type that is compatible with the actual element type of `array`. In `Main`, the first two invocations of `Fill` succeed, but the third invocation causes a `System.ArrayTypeMismatchException` to be thrown upon executing the first assignment to `array[i]`. The exception occurs because a boxed `int` cannot be stored in a `string` array.

end example

Array covariance specifically does not extend to arrays of *value_types*. For example, no conversion exists that permits an `int[]` to be treated as an `object[]`.

16.7 Array initializers

Array initializers may be specified in field declarations (§14.5), local variable declarations (§12.6.2), and array creation expressions (§11.7.15.5):

ANTLR

```

array_initializer
: '{' variable_initializer_list? '}'
| '{' variable_initializer_list ',' '}'
;

variable_initializer_list
: variable_initializer (',' variable_initializer)*
;

variable_initializer
: expression
| array_initializer
;

```

An array initializer consists of a sequence of variable initializers, enclosed by “{” and “}” tokens and separated by “,” tokens. Each variable initializer is an expression or, in the case of a multi-dimensional array, a nested array initializer.

The context in which an array initializer is used determines the type of the array being initialized. In an array creation expression, the array type immediately precedes the initializer, or is inferred from the expressions in the array initializer. In a field or variable declaration, the array type is the type of the field or variable being declared. When an array initializer is used in a field or variable declaration,

```
C#
```

```
int[] a = {0, 2, 4, 6, 8};
```

it is simply shorthand for an equivalent array creation expression:

```
C#
```

```
int[] a = new int[] {0, 2, 4, 6, 8};
```

For a single-dimensional array, the array initializer shall consist of a sequence of expressions, each having an implicit conversion to the element type of the array (§10.2). The expressions initialize array elements in increasing order, starting with the element at index zero. The number of expressions in the array initializer determines the length of the array instance being created.

Example: The array initializer above creates an `int[]` instance of length 5 and then initializes the instance with the following values:

```
C#
```

```
a[0] = 0; a[1] = 2; a[2] = 4; a[3] = 6; a[4] = 8;
```

end example

For a multi-dimensional array, the array initializer shall have as many levels of nesting as there are dimensions in the array. The outermost nesting level corresponds to the leftmost dimension and the innermost nesting level corresponds to the rightmost dimension. The length of each dimension of the array is determined by the number of elements at the corresponding nesting level in the array initializer. For each nested array initializer, the number of elements shall be the same as the other array initializers at the same level.

Example: The example:

```
C#
```

```
int[,] b = {{0, 1}, {2, 3}, {4, 5}, {6, 7}, {8, 9}};
```

creates a two-dimensional array with a length of five for the leftmost dimension and a length of two for the rightmost dimension:

```
C#
```

```
int[,] b = new int[5, 2];
```

and then initializes the array instance with the following values:

```
C#
```

```
b[0, 0] = 0; b[0, 1] = 1;  
b[1, 0] = 2; b[1, 1] = 3;  
b[2, 0] = 4; b[2, 1] = 5;  
b[3, 0] = 6; b[3, 1] = 7;  
b[4, 0] = 8; b[4, 1] = 9;
```

end example

If a dimension other than the rightmost is given with length zero, the subsequent dimensions are assumed to also have length zero.

Example:

```
C#
```

```
int[,] c = {};
```

creates a two-dimensional array with a length of zero for both the leftmost and the rightmost dimension:

```
C#
```

```
int[,] c = new int[0, 0];
```

end example

When an array creation expression includes both explicit dimension lengths and an array initializer, the lengths shall be constant expressions and the number of elements at each nesting level shall match the corresponding dimension length.

Example: Here are some examples:

C#

```
int i = 3;
int[] x = new int[3] {0, 1, 2}; // OK
int[] y = new int[i] {0, 1, 2}; // Error, i not a constant
int[] z = new int[3] {0, 1, 2, 3}; // Error, length/initializer mismatch
```

Here, the initializer for `y` results in a compile-time error because the dimension length expression is not a constant, and the initializer for `z` results in a compile-time error because the length and the number of elements in the initializer do not agree.

end example

Note: C# allows a trailing comma at the end of an *array_initializer*. This syntax provides flexibility in adding or deleting members from such a list, and simplifies machine generation of such lists. *end note*

17 Interfaces

Article • 2023-01-12 • 32 minutes to read

17.1 General

An interface defines a contract. A class or struct that implements an interface shall adhere to its contract. An interface may inherit from multiple base interfaces, and a class or struct may implement multiple interfaces.

Interfaces can contain methods, properties, events, and indexers. The interface itself does not provide implementations for the members that it declares. The interface merely specifies the members that shall be supplied by classes or structs that implement the interface.

17.2 Interface declarations

17.2.1 General

An *interface_declaration* is a *type_declaration* (§13.7) that declares a new interface type.

ANTLR

```
interface_declaration
    : attributes? interface_modifier* 'partial'? 'interface'
      identifier variant_type_parameter_list? interface_base?
      type_parameter_constraints_clause* interface_body ';'
    ;
```

An *interface_declaration* consists of an optional set of *attributes* (§21), followed by an optional set of *interface_modifiers* (§17.2.2), followed by an optional partial modifier (§14.2.7), followed by the keyword `interface` and an *identifier* that names the interface, followed by an optional *variant_type_parameter_list* specification (§17.2.3), followed by an optional *interface_base* specification (§17.2.4), followed by an optional *type_parameter_constraints_clauses* specification (§14.2.5), followed by an *interface_body* (§17.3), optionally followed by a semicolon.

An interface declaration shall not supply a *type_parameter_constraints_clauses* unless it also supplies a *type_parameter_list*.

An interface declaration that supplies a *type_parameter_list* is a generic interface declaration. Additionally, any interface nested inside a generic class declaration or a

generic struct declaration is itself a generic interface declaration, since type arguments for the containing type shall be supplied to create a constructed type (§8.4).

17.2.2 Interface modifiers

An *interface_declaration* may optionally include a sequence of interface modifiers:

ANTLR

```
interface_modifier
  : 'new'
  | 'public'
  | 'protected'
  | 'internal'
  | 'private'
  | unsafe_modifier // unsafe code support
  ;
```

unsafe_modifier (§22.2) is only available in unsafe code (§22).

It is a compile-time error for the same modifier to appear multiple times in an interface declaration.

The `new` modifier is only permitted on interfaces defined within a class. It specifies that the interface hides an inherited member by the same name, as described in §14.3.5.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the interface. Depending on the context in which the interface declaration occurs, only some of these modifiers might be permitted (§7.5.2). When a partial type declaration (§14.2.7) includes an accessibility specification (via the `public`, `protected`, `internal`, and `private` modifiers), the rules in §14.2.2 apply.

17.2.3 Variant type parameter lists

17.2.3.1 General

Variant type parameter lists can only occur on interface and delegate types. The difference from ordinary *type_parameter_lists* is the optional *variance_annotation* on each type parameter.

ANTLR

```
variant_type_parameter_list
  : '<' variant_type_parameters '>'
```

```
;
```

ANTLR

```
variant_type_parameters
  : attributes? variance_annotation? type_parameter
  | variant_type_parameters ',' attributes? variance_annotation?
  type_parameter
  ;
```

ANTLR

```
variance_annotation
  : 'in'
  | 'out'
  ;
```

If the variance annotation is `out`, the type parameter is said to be *covariant*. If the variance annotation is `in`, the type parameter is said to be *contravariant*. If there is no variance annotation, the type parameter is said to be *invariant*.

Example: In the following:

C#

```
interface C<out X, in Y, Z>
{
    X M(Y y);
    Z P { get; set; }
}
```

`X` is covariant, `Y` is contravariant and `Z` is invariant.

end example

If a generic interface is declared in multiple parts (§14.2.3), each partial declaration shall specify the same variance for each type parameter.

17.2.3.2 Variance safety

The occurrence of variance annotations in the type parameter list of a type restricts the places where types can occur within the type declaration.

A type `T` is *output-unsafe* if one of the following holds:

- T is a contravariant type parameter
- T is an array type with an output-unsafe element type
- T is an interface or delegate type S_i, \dots, A_e constructed from a generic type $S\langle X_i, \dots, X_e \rangle$ where for at least one A_i one of the following holds:
 - X_i is covariant or invariant and A_i is output-unsafe.
 - X_i is contravariant or invariant and A_i is input-unsafe.

A type T is **input-unsafe** if one of the following holds:

- T is a covariant type parameter
- T is an array type with an input-unsafe element type
- T is an interface or delegate type $S\langle A_i, \dots, A_e \rangle$ constructed from a generic type $S\langle X_i, \dots, X_e \rangle$ where for at least one A_i one of the following holds:
 - X_i is covariant or invariant and A_i is input-unsafe.
 - X_i is contravariant or invariant and A_i is output-unsafe.

Intuitively, an output-unsafe type is prohibited in an output position, and an input-unsafe type is prohibited in an input position.

A type is **output-safe** if it is not output-unsafe, and **input-safe** if it is not input-unsafe.

17.2.3.3 Variance conversion

The purpose of variance annotations is to provide for more lenient (but still type safe) conversions to interface and delegate types. To this end the definitions of implicit (§10.2) and explicit conversions (§10.3) make use of the notion of variance-convertibility, which is defined as follows:

A type $T\langle A_i, \dots, A_v \rangle$ is variance-convertible to a type $T\langle B_i, \dots, B_v \rangle$ if T is either an interface or a delegate type declared with the variant type parameters $T\langle X_i, \dots, X_v \rangle$, and for each variant type parameter X_i one of the following holds:

- X_i is covariant and an implicit reference or identity conversion exists from A_i to B_i
- X_i is contravariant and an implicit reference or identity conversion exists from B_i to A_i
- X_i is invariant and an identity conversion exists from A_i to B_i

17.2.4 Base interfaces

An interface can inherit from zero or more interface types, which are called the **explicit base interfaces** of the interface. When an interface has one or more explicit base interfaces, then in the declaration of that interface, the interface identifier is followed by a colon and a comma-separated list of base interface types.

ANTLR

```
interface_base
    : ':' interface_type_list
    ;
```

The explicit base interfaces can be constructed interface types (§8.4, §17.2). A base interface cannot be a type parameter on its own, though it can involve the type parameters that are in scope.

For a constructed interface type, the explicit base interfaces are formed by taking the explicit base interface declarations on the generic type declaration, and substituting, for each *type_parameter* in the base interface declaration, the corresponding *type_argument* of the constructed type.

The explicit base interfaces of an interface shall be at least as accessible as the interface itself (§7.5.5).

Note: For example, it is a compile-time error to specify a `private` or `internal` interface in the *interface_base* of a `public` interface. *end note*

It is a compile-time error for an interface to directly or indirectly inherit from itself.

The **base interfaces** of an interface are the explicit base interfaces and their base interfaces. In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on. An interface inherits all members of its base interfaces.

Example: In the following code

```
C#

interface IControl
{
    void Paint();
}

interface ITextBox : IControl
{
    void SetText(string text);
}
```

```

interface IListBox : IControl
{
    void SetItems(string[] items);
}

interface IComboBox: ITextBox, IListBox {}

```

the base interfaces of `IComboBox` are `IControl`, `ITextBox`, and `IListBox`. In other words, the `IComboBox` interface above inherits members `SetText` and `SetItems` as well as `Paint`.

end example

Members inherited from a constructed generic type are inherited after type substitution. That is, any constituent types in the member have the base class declaration's type parameters replaced with the corresponding type arguments used in the *class_base* specification.

Example: In the following code

```

C#

interface IBase<T>
{
    T[] Combine(T a, T b);
}

interface IDerived : IBase<string[,]>
{
    // Inherited: string[,] Combine(string[,] a, string[,] b);
}

```

the interface `IDerived` inherits the `Combine` method after the type parameter `T` is replaced with `string[,]`.

end example

A class or struct that implements an interface also implicitly implements all of the interface's base interfaces.

The handling of interfaces on multiple parts of a partial interface declaration ([§14.2.7](#)) are discussed further in [§14.2.4.3](#).

Every base interface of an interface shall be output-safe ([§17.2.3.2](#)).

17.3 Interface body

The *interface_body* of an interface defines the members of the interface.

ANTLR

```
interface_body
    : '{' interface_member_declaration* '}'
    ;
```

17.4 Interface members

17.4.1 General

The members of an interface are the members inherited from the base interfaces and the members declared by the interface itself.

ANTLR

```
interface_member_declaration
    : interface_method_declaration
    | interface_property_declaration
    | interface_event_declaration
    | interface_indexer_declaration
    ;
```

An interface declaration declares zero or more members. The members of an interface shall be methods, properties, events, or indexers. An interface cannot contain constants, fields, operators, instance constructors, finalizers, or types, nor can an interface contain static members of any kind.

All interface members implicitly have public access. It is a compile-time error for interface member declarations to include any modifiers.

An *interface_declaration* creates a new declaration space (§7.3), and the type parameters and *interface_member_declarations* immediately contained by the *interface_declaration* introduce new members into this declaration space. The following rules apply to *interface_member_declarations*:

- The name of a type parameter in the *type_parameter_list* of an interface declaration shall differ from the names of all other type parameters in the same *type_parameter_list* and shall differ from the names of all members of the interface.

- The name of a method shall differ from the names of all properties and events declared in the same interface. In addition, the signature (§7.6) of a method shall differ from the signatures of all other methods declared in the same interface, and two methods declared in the same interface may not have signatures that differ solely by `ref` and `out`.
- The name of a property or event shall differ from the names of all other members declared in the same interface.
- The signature of an indexer shall differ from the signatures of all other indexers declared in the same interface.

The inherited members of an interface are specifically not part of the declaration space of the interface. Thus, an interface is allowed to declare a member with the same name or signature as an inherited member. When this occurs, the derived interface member is said to *hide* the base interface member. Hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived interface member shall include a `new` modifier to indicate that the derived member is intended to hide the base member. This topic is discussed further in §7.7.2.3.

If a `new` modifier is included in a declaration that doesn't hide an inherited member, a warning is issued to that effect. This warning is suppressed by removing the `new` modifier.

Note: The members in class `object` are not, strictly speaking, members of any interface (§17.4). However, the members in class `object` are available via member lookup in any interface type (§11.5). *end note*

The set of members of an interface declared in multiple parts (§14.2.7) is the union of the members declared in each part. The bodies of all parts of the interface declaration share the same declaration space (§7.3), and the scope of each member (§7.7) extends to the bodies of all the parts.

17.4.2 Interface methods

Interface methods are declared using *interface_method_declarations*:

ANTLR

```
interface_method_declaration
: attributes? 'new'? return_type identifier type_parameter_list?
  '(' formal_parameter_list? ')' type_parameter_constraints_clause* ';'
;
```

The *attributes*, *return_type*, *identifier*, and *formal_parameter_list* of an interface method declaration have the same meaning as those of a method declaration in a class (§14.6). An interface method declaration is not permitted to specify a method body, and the declaration therefore always ends with a semicolon. An *interface_method_declaration* shall not have *type_parameter_constraints_clauses* unless it also has a *type_parameter_list*.

All formal parameter types of an interface method shall be input-safe (§17.2.3.2), and the return type shall be either `void` or output-safe. In addition, any output or reference formal parameter types shall also be output-safe.

Note: Output parameters are required to be input-safe due to common implementation restrictions. *end note*

Furthermore, each class type constraint, interface type constraint and type parameter constraint on any type parameters of the method shall be input-safe.

Furthermore, each class type constraint, interface type constraint and type parameter constraint on any type parameter of the method shall be input-safe.

These rules ensure that any covariant or contravariant usage of the interface remains typesafe.

Example:

```
C#  
  
interface I<out T>  
{  
    void M<U>() where U : T;    // Error  
}
```

is ill-formed because the usage of `T` as a type parameter constraint on `U` is not input-safe.

Were this restriction not in place it would be possible to violate type safety in the following manner:

```
C#  
  
class B {}  
class D : B {}  
class E : B {}  
class C : I<D>  
{
```

```

    public void M<U>() {...}
}

...

I<B> b = new C();
b.M<E>();

```

This is actually a call to `C.M<E>`. But that call requires that `E` derive from `D`, so type safety would be violated here.

end example

17.4.3 Interface properties

Interface properties are declared using *interface_property_declarations*:

ANTLR

```

interface_property_declaration
: attributes? 'new'? type identifier '{' interface_accessors '}'
;

```

ANTLR

```

interface_accessors
: attributes? 'get' ';'
| attributes? 'set' ';'
| attributes? 'get' ';' attributes? 'set' ';'
| attributes? 'set' ';' attributes? 'get' ';'
;

```

The *attributes*, *type*, and *identifier* of an interface property declaration have the same meaning as those of a property declaration in a class (§14.7).

The accessors of an interface property declaration correspond to the accessors of a class property declaration (§14.7.3), except that the accessor body shall always be a semicolon. Thus, the accessors simply indicate whether the property is read-write, read-only, or write-only.

The type of an interface property shall be output-safe if there is a get accessor, and shall be input-safe if there is a set accessor.

17.4.4 Interface events

Interface events are declared using *interface_event_declarations*:

ANTLR

```
interface_event_declaration
    : attributes? 'new'? 'event' type identifier ';'
    ;
```

The *attributes*, *type*, and *identifier* of an interface event declaration have the same meaning as those of an event declaration in a class (§14.8).

The type of an interface event shall be input-safe.

17.4.5 Interface indexers

Interface indexers are declared using *interface_indexer_declarations*:

ANTLR

```
interface_indexer_declaration:
    attributes? 'new'? type 'this' '[' formal_parameter_list ']'
    '{' interface_accessors '}'
    ;
```

The *attributes*, *type*, and *formal_parameter_list* of an interface indexer declaration have the same meaning as those of an indexer declaration in a class (§14.9).

The accessors of an interface indexer declaration correspond to the accessors of a class indexer declaration (§14.9), except that the accessor body shall always be a semicolon. Thus, the accessors simply indicate whether the indexer is read-write, read-only, or write-only.

All the formal parameter types of an interface indexer shall be input-safe (§17.2.3.2). In addition, any output or reference formal parameter types shall also be output-safe.

Note: Output parameters are required to be input-safe due to common implementation restrictions. *end note*

The type of an interface indexer shall be output-safe if there is a get accessor, and shall be input-safe if there is a set accessor.

17.4.6 Interface member access

Interface members are accessed through member access (§11.7.6) and indexer access (§11.7.10.3) expressions of the form `I.M` and `I[A]`, where `I` is an interface type, `M` is a method, property, or event of that interface type, and `A` is an indexer argument list.

For interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effects of the member lookup (§11.5), method invocation (§11.7.8.2), and indexer access (§11.7.10.3) rules are exactly the same as for classes and structs: More derived members hide less derived members with the same name or signature. However, for multiple-inheritance interfaces, ambiguities can occur when two or more unrelated base interfaces declare members with the same name or signature. This subclass shows several examples, some of which lead to ambiguities and others which don't. In all cases, explicit casts can be used to resolve the ambiguities.

Example: In the following code

```
C#  
  
interface IList  
{  
    int Count { get; set; }  
}  
  
interface ICounter  
{  
    void Count(int i);  
}  
  
interface IListCounter : IList, ICounter {}  
  
class C  
{  
    void Test(IListCounter x)  
    {  
        x.Count(1);           // Error  
        x.Count = 1;         // Error  
        ((IList)x).Count = 1; // Ok, invokes IList.Count.set  
        ((ICounter)x).Count(1); // Ok, invokes ICounter.Count  
    }  
}
```

the first two statements cause compile-time errors because the member lookup (§11.5) of `Count` in `IListCounter` is ambiguous. As illustrated by the example, the ambiguity is resolved by casting `x` to the appropriate base interface type. Such casts have no run-time costs—they merely consist of viewing the instance as a less derived type at compile-time.

end example

Example: In the following code

```
C#  
  
interface IInteger  
{  
    void Add(int i);  
}  
  
interface IDouble  
{  
    void Add(double d);  
}  
  
interface INumber : IInteger, IDouble {}  
  
class C  
{  
    void Test(INumber n)  
    {  
        n.Add(1);           // Invokes IInteger.Add  
        n.Add(1.0);        // Only IDouble.Add is applicable  
        ((IInteger)n).Add(1); // Only IInteger.Add is a candidate  
        ((IDouble)n).Add(1); // Only IDouble.Add is a candidate  
    }  
}
```

the invocation `n.Add(1)` selects `IInteger.Add` by applying overload resolution rules of §11.6.4. Similarly, the invocation `n.Add(1.0)` selects `IDouble.Add`. When explicit casts are inserted, there is only one candidate method, and thus no ambiguity.

end example

Example: In the following code

```
C#  
  
interface IBase  
{  
    void F(int i);  
}  
  
interface ILeft : IBase  
{  
    new void F(int i);  
}
```

```

interface IRight : IBase
{
    void G();
}

interface IDerived : ILeft, IRight {}

class A
{
    void Test(IDerived d)
    {
        d.F(1);           // Invokes ILeft.F
        ((IBase)d).F(1);  // Invokes IBase.F
        ((ILeft)d).F(1);  // Invokes ILeft.F
        ((IRight)d).F(1); // Invokes IBase.F
    }
}

```

the `IBase.F` member is hidden by the `ILeft.F` member. The invocation `d.F(1)` thus selects `ILeft.F`, even though `IBase.F` appears to not be hidden in the access path that leads through `IRight`.

The intuitive rule for hiding in multiple-inheritance interfaces is simply this: If a member is hidden in any access path, it is hidden in all access paths. Because the access path from `IDerived` to `ILeft` to `IBase` hides `IBase.F`, the member is also hidden in the access path from `IDerived` to `IRight` to `IBase`.

end example

17.5 Qualified interface member names

An interface member is sometimes referred to by its *qualified interface member name*. The qualified name of an interface member consists of the name of the interface in which the member is declared, followed by a dot, followed by the name of the member. The qualified name of a member references the interface in which the member is declared.

Example: Given the declarations

```

C#

interface IControl
{
    void Paint();
}

interface ITextBox : IControl

```

```
{  
    void SetText(string text);  
}
```

the qualified name of `Paint` is `IControl.Paint` and the qualified name of `SetText` is `ITextBox.SetText`. In the example above, it is not possible to refer to `Paint` as `ITextBox.Paint`.

end example

When an interface is part of a namespace, a qualified interface member name can include the namespace name.

Example:

```
C#  
  
namespace System  
{  
    public interface ICloneable  
    {  
        object Clone();  
    }  
}
```

Within the `System` namespace, both `ICloneable.Clone` and `System.ICloneable.Clone` are qualified interface member names for the `Clone` method.

end example

17.6 Interface implementations

17.6.1 General

Interfaces may be implemented by classes and structs. To indicate that a class or struct directly implements an interface, the interface is included in the base class list of the class or struct.

Example:

```
C#  
  
interface ICloneable  
{
```

```

    object Clone();
}

interface IComparable
{
    int CompareTo(object other);
}

class ListEntry : ICloneable, IComparable
{
    public object Clone() {...}
    public int CompareTo(object other) {...}
}

```

end example

A class or struct that directly implements an interface also implicitly implements all of the interface's base interfaces. This is true even if the class or struct doesn't explicitly list all base interfaces in the base class list.

Example:

```

C#

interface IControl
{
    void Paint();
}

interface ITextBox : IControl
{
    void SetText(string text);
}

class TextBox : ITextBox
{
    public void Paint() {...}
    public void SetText(string text) {...}
}

```

Here, class `TextBox` implements both `IControl` and `ITextBox`.

end example

When a class `C` directly implements an interface, all classes derived from `C` also implement the interface implicitly.

The base interfaces specified in a class declaration can be constructed interface types (§8.4, §17.2).

Example: The following code illustrates how a class can implement constructed interface types:

```
C#  
  
class C<U, V> {}  
interface I1<V> {}  
class D : C<string, int>, I1<string> {}  
class E<T> : C<int, T>, I1<T> {}
```

end example

The base interfaces of a generic class declaration shall satisfy the uniqueness rule described in §17.6.3.

17.6.2 Explicit interface member implementations

For purposes of implementing interfaces, a class or struct may declare ***explicit interface member implementations***. An explicit interface member implementation is a method, property, event, or indexer declaration that references a qualified interface member name.

Example:

```
C#  
  
interface IList<T>  
{  
    T[] GetElements();  
}  
  
interface IDictionary<K, V>  
{  
    V this[K key] { get; }  
    void Add(K key, V value);  
}  
  
class List<T> : IList<T>, IDictionary<int, T>  
{  
    T[] IList<T>. GetElements() {...}  
    T IDictionary<int, T>.this[int index] {...}  
    void IDictionary<int, T>.Add(int index, T value) {...}  
}
```

Here `IDictionary<int,T>.this` and `IDictionary<int,T>.Add` are explicit interface member implementations.

end example

Example: In some cases, the name of an interface member might not be appropriate for the implementing class, in which case, the interface member may be implemented using explicit interface member implementation. A class implementing a file abstraction, for example, would likely implement a `Close` member function that has the effect of releasing the file resource, and implement the `Dispose` method of the `IDisposable` interface using explicit interface member implementation:

```
C#  
  
interface IDisposable  
{  
    void Dispose();  
}  
  
class MyFile : IDisposable  
{  
    void IDisposable.Dispose() => Close();  
  
    public void Close()  
    {  
        // Do what's necessary to close the file  
        System.GC.SuppressFinalize(this);  
    }  
}
```

end example

It is not possible to access an explicit interface member implementation through its qualified interface member name in a method invocation, property access, event access, or indexer access. An explicit interface member implementation can only be accessed through an interface instance, and is in that case referenced simply by its member name.

It is a compile-time error for an explicit interface member implementation to include any modifiers (§14.6) other than `extern` or `async`.

It is a compile-time error for an explicit interface method implementation to include `type_parameter_constraints_clauses`. The constraints for a generic explicit interface method implementation are inherited from the interface method.

Note: Explicit interface member implementations have different accessibility characteristics than other members. Because explicit interface member implementations are never accessible through a qualified interface member name in a method invocation or a property access, they are in a sense private. However, since they can be accessed through the interface, they are in a sense also as public as the interface in which they are declared. Explicit interface member implementations serve two primary purposes:

- Because explicit interface member implementations are not accessible through class or struct instances, they allow interface implementations to be excluded from the public interface of a class or struct. This is particularly useful when a class or struct implements an internal interface that is of no interest to a consumer of that class or struct.
- Explicit interface member implementations allow disambiguation of interface members with the same signature. Without explicit interface member implementations it would be impossible for a class or struct to have different implementations of interface members with the same signature and return type, as would it be impossible for a class or struct to have any implementation at all of interface members with the same signature but with different return types.

end note

For an explicit interface member implementation to be valid, the class or struct shall name an interface in its base class list that contains a member whose qualified interface member name, type, number of type parameters, and parameter types exactly match those of the explicit interface member implementation. If an interface function member has a parameter array, the corresponding parameter of an associated explicit interface member implementation is allowed, but not required, to have the `params` modifier. If the interface function member does not have a parameter array then an associated explicit interface member implementation shall not have a parameter array.

Example: Thus, in the following class

```
C#  
  
class Shape : ICloneable  
{  
    object ICloneable.Clone() {...}  
    int IComparable.CompareTo(object other) {...} // invalid  
}
```

the declaration of `IComparable.CompareTo` results in a compile-time error because `IComparable` is not listed in the base class list of `Shape` and is not a base interface of `ICloneable`. Likewise, in the declarations

```
C#  
  
class Shape : ICloneable  
{  
    object ICloneable.Clone() {...}  
}  
  
class Ellipse : Shape  
{  
    object ICloneable.Clone() {...} // invalid  
}
```

the declaration of `ICloneable.Clone` in `Ellipse` results in a compile-time error because `ICloneable` is not explicitly listed in the base class list of `Ellipse`.

end example

The qualified interface member name of an explicit interface member implementation shall reference the interface in which the member was declared.

Example: Thus, in the declarations

```
C#  
  
interface IControl  
{  
    void Paint();  
}  
  
interface ITextBox : IControl  
{  
    void SetText(string text);  
}  
  
class TextBox : ITextBox  
{  
    void IControl.Paint() {...}  
    void ITextBox.SetText(string text) {...}  
}
```

the explicit interface member implementation of `Paint` must be written as `IControl.Paint`, not `ITextBox.Paint`.

end example

17.6.3 Uniqueness of implemented interfaces

The interfaces implemented by a generic type declaration shall remain unique for all possible constructed types. Without this rule, it would be impossible to determine the correct method to call for certain constructed types.

Example: Suppose a generic class declaration were permitted to be written as follows:

```
C#  
  
interface I<T>  
{  
    void F();  
}  
  
class X<U ,V> : I<U>, I<V> // Error: I<U> and I<V> conflict  
{  
    void I<U>.F() {...}  
    void I<V>.F() {...}  
}
```

Were this permitted, it would be impossible to determine which code to execute in the following case:

```
C#  
  
I<int> x = new X<int, int>();  
x.F();
```

end example

To determine if the interface list of a generic type declaration is valid, the following steps are performed:

- Let **L** be the list of interfaces directly specified in a generic class, struct, or interface declaration **C**.
- Add to **L** any base interfaces of the interfaces already in **L**.
- Remove any duplicates from **L**.
- If any possible constructed type created from **C** would, after type arguments are substituted into **L**, cause two interfaces in **L** to be identical, then the declaration

of `C` is invalid. Constraint declarations are not considered when determining all possible constructed types.

Note: In the class declaration `X` above, the interface list `L` consists of `I<U>` and `I<V>`. The declaration is invalid because any constructed type with `U` and `V` being the same type would cause these two interfaces to be identical types. *end note*

It is possible for interfaces specified at different inheritance levels to unify:

```
C#  
  
interface I<T>  
{  
    void F();  
}  
  
class Base<U> : I<U>  
{  
    void I<U>.F() {...}  
}  
  
class Derived<U, V> : Base<U>, I<V> // Ok  
{  
    void I<V>.F() {...}  
}
```

This code is valid even though `Derived<U,V>` implements both `I<U>` and `I<V>`. The code

```
C#  
  
I<int> x = new Derived<int, int>();  
x.F();
```

invokes the method in `Derived`, since `Derived<int,int>` effectively re-implements `I<int>` (§17.6.7).

17.6.4 Implementation of generic methods

When a generic method implicitly implements an interface method, the constraints given for each method type parameter shall be equivalent in both declarations (after any interface type parameters are replaced with the appropriate type arguments), where method type parameters are identified by ordinal positions, left to right.

Example: In the following code:

C#

```
interface I<X, Y, Z>
{
    void F<T>(T t) where T : X;
    void G<T>(T t) where T : Y;
    void H<T>(T t) where T : Z;
}

class C : I<object, C, string>
{
    public void F<T>(T t) {...} // Ok
    public void G<T>(T t) where T : C {...} // Ok
    public void H<T>(T t) where T : string {...} // Error
}
```

the method `C.F<T>` implicitly implements `I<object,C,string>.F<T>`. In this case, `C.F<T>` is not required (nor permitted) to specify the constraint `T: object` since `object` is an implicit constraint on all type parameters. The method `C.G<T>` implicitly implements `I<object,C,string>.G<T>` because the constraints match those in the interface, after the interface type parameters are replaced with the corresponding type arguments. The constraint for method `C.H<T>` is an error because sealed types (`string` in this case) cannot be used as constraints. Omitting the constraint would also be an error since constraints of implicit interface method implementations are required to match. Thus, it is impossible to implicitly implement `I<object,C,string>.H<T>`. This interface method can only be implemented using an explicit interface member implementation:

C#

```
class C : I<object, C, string>
{
    ...
    public void H<U>(U u) where U : class {...}

    void I<object, C, string>.H<T>(T t)
    {
        string s = t; // Ok
        H<T>(t);
    }
}
```

In this case, the explicit interface member implementation invokes a public method having strictly weaker constraints. The assignment from `t` to `s` is valid since `T` inherits a constraint of `T: string`, even though this constraint is not expressible in source code. *end example*

Note: When a generic method explicitly implements an interface method no constraints are allowed on the implementing method (§14.7.1, §17.6.2). *end note*

17.6.5 Interface mapping

A class or struct shall provide implementations of all members of the interfaces that are listed in the base class list of the class or struct. The process of locating implementations of interface members in an implementing class or struct is known as *interface mapping*.

Interface mapping for a class or struct `C` locates an implementation for each member of each interface specified in the base class list of `C`. The implementation of a particular interface member `I.M`, where `I` is the interface in which the member `M` is declared, is determined by examining each class or struct `S`, starting with `C` and repeating for each successive base class of `C`, until a match is located:

- If `S` contains a declaration of an explicit interface member implementation that matches `I` and `M`, then this member is the implementation of `I.M`.
- Otherwise, if `S` contains a declaration of a non-static public member that matches `M`, then this member is the implementation of `I.M`. If more than one member matches, it is unspecified which member is the implementation of `I.M`. This situation can only occur if `S` is a constructed type where the two members as declared in the generic type have different signatures, but the type arguments make their signatures identical.

A compile-time error occurs if implementations cannot be located for all members of all interfaces specified in the base class list of `C`. The members of an interface include those members that are inherited from base interfaces.

Members of a constructed interface type are considered to have any type parameters replaced with the corresponding type arguments as specified in §14.3.3.

Example: For example, given the generic interface declaration:

```
C#  
  
interface I<T>  
{  
    T F(int x, T[,] y);  
    T this[int y] { get; }  
}
```

the constructed interface `I<string[]>` has the members:

C#

```
string[] F(int x, string[,][[] y);  
string[] this[int y] { get; }
```

end example

For purposes of interface mapping, a class or struct member **A** matches an interface member **B** when:

- **A** and **B** are methods, and the name, type, and formal parameter lists of **A** and **B** are identical.
- **A** and **B** are properties, the name and type of **A** and **B** are identical, and **A** has the same accessors as **B** (**A** is permitted to have additional accessors if it is not an explicit interface member implementation).
- **A** and **B** are events, and the name and type of **A** and **B** are identical.
- **A** and **B** are indexers, the type and formal parameter lists of **A** and **B** are identical, and **A** has the same accessors as **B** (**A** is permitted to have additional accessors if it is not an explicit interface member implementation).

Notable implications of the interface-mapping algorithm are:

- Explicit interface member implementations take precedence over other members in the same class or struct when determining the class or struct member that implements an interface member.
- Neither non-public nor static members participate in interface mapping.

Example: In the following code

C#

```
interface ICloneable  
{  
    object Clone();  
}  
  
class C : ICloneable  
{  
    object ICloneable.Clone() {...}  
    public object Clone() {...}  
}
```

the `ICloneable.Clone` member of `C` becomes the implementation of `Clone` in 'ICloneable' because explicit interface member implementations take precedence

over other members.

end example

If a class or struct implements two or more interfaces containing a member with the same name, type, and parameter types, it is possible to map each of those interface members onto a single class or struct member.

Example:

```
C#  
  
interface IControl  
{  
    void Paint();  
}  
  
interface IForm  
{  
    void Paint();  
}  
  
class Page : IControl, IForm  
{  
    public void Paint() {...}  
}
```

Here, the `Paint` methods of both `IControl` and `IForm` are mapped onto the `Paint` method in `Page`. It is of course also possible to have separate explicit interface member implementations for the two methods.

end example

If a class or struct implements an interface that contains hidden members, then some members may need to be implemented through explicit interface member implementations.

Example:

```
C#  
  
interface IBase  
{  
    int P { get; }  
}  
  
interface IDerived : IBase
```

```
{
    new int P();
}
```

An implementation of this interface would require at least one explicit interface member implementation, and would take one of the following forms

```
C#

class C1 : IDerived
{
    int IBase.P { get; }
    int IDerived.P() {...}
}
class C2 : IDerived
{
    public int P { get; }
    int IDerived.P() {...}
}
class C3 : IDerived
{
    int IBase.P { get; }
    public int P() {...}
}
```

end example

When a class implements multiple interfaces that have the same base interface, there can be only one implementation of the base interface.

Example: In the following code

```
C#

interface IControl
{
    void Paint();
}

interface ITextBox : IControl
{
    void SetText(string text);
}

interface IListBox : IControl
{
    void SetItems(string[] items);
}

class ComboBox : IControl, ITextBox, IListBox
```

```

{
    void IControl.Paint() {...}
    void ITextBox.SetText(string text) {...}
    void IListBox.SetItems(string[] items) {...}
}

```

it is not possible to have separate implementations for the `IControl` named in the base class list, the `IControl` inherited by `ITextBox`, and the `IControl` inherited by `IListBox`. Indeed, there is no notion of a separate identity for these interfaces.

Rather, the implementations of `ITextBox` and `IListBox` share the same implementation of `IControl`, and `ComboBox` is simply considered to implement three interfaces, `IControl`, `ITextBox`, and `IListBox`.

end example

The members of a base class participate in interface mapping.

Example: In the following code

```

C#

interface Interface1
{
    void F();
}

class Class1
{
    public void F() {}
    public void G() {}
}

class Class2 : Class1, Interface1
{
    public new void G() {}
}

```

the method `F` in `Class1` is used in `Class2's` implementation of `Interface1`.

end example

17.6.6 Interface implementation inheritance

A class inherits all interface implementations provided by its base classes.

Without explicitly re-implementing an interface, a derived class cannot in any way alter the interface mappings it inherits from its base classes.

Example: In the declarations

```
C#  
  
interface IControl  
{  
    void Paint();  
}  
  
class Control : IControl  
{  
    public void Paint() {...}  
}  
  
class TextBox : Control  
{  
    public new void Paint() {...}  
}
```

the `Paint` method in `TextBox` hides the `Paint` method in `Control`, but it does not alter the mapping of `Control.Paint` onto `IControl.Paint`, and calls to `Paint` through class instances and interface instances will have the following effects

```
C#  
  
Control c = new Control();  
TextBox t = new TextBox();  
IControl ic = c;  
IControl it = t;  
c.Paint(); // invokes Control.Paint();  
t.Paint(); // invokes TextBox.Paint();  
ic.Paint(); // invokes Control.Paint();  
it.Paint(); // invokes Control.Paint();
```

end example

However, when an interface method is mapped onto a virtual method in a class, it is possible for derived classes to override the virtual method and alter the implementation of the interface.

Example: Rewriting the declarations above to

```
C#
```

```

interface IControl
{
    void Paint();
}

class Control : IControl
{
    public virtual void Paint() {...}
}

class TextBox : Control
{
    public override void Paint() {...}
}

```

the following effects will now be observed

```

C#

Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;
c.Paint(); // invokes Control.Paint();
t.Paint(); // invokes TextBox.Paint();
ic.Paint(); // invokes Control.Paint();
it.Paint(); // invokes TextBox.Paint();

```

end example

Since explicit interface member implementations cannot be declared virtual, it is not possible to override an explicit interface member implementation. However, it is perfectly valid for an explicit interface member implementation to call another method, and that other method can be declared virtual to allow derived classes to override it.

Example:

```

C#

interface IControl
{
    void Paint();
}

class Control : IControl
{
    void IControl.Paint() { PaintControl(); }
    protected virtual void PaintControl() {...}
}

```

```
class TextBox : Control
{
    protected override void PaintControl() {...}
}
```

Here, classes derived from `Control` can specialize the implementation of `IControl.Paint` by overriding the `PaintControl` method.

end example

17.6.7 Interface re-implementation

A class that inherits an interface implementation is permitted to *re-implement* the interface by including it in the base class list.

A re-implementation of an interface follows exactly the same interface mapping rules as an initial implementation of an interface. Thus, the inherited interface mapping has no effect whatsoever on the interface mapping established for the re-implementation of the interface.

Example: In the declarations

```
C#

interface IControl
{
    void Paint();
}

class Control : IControl
{
    void IControl.Paint() {...}
}

class MyControl : Control, IControl
{
    public void Paint() {}
}
```

the fact that `Control` maps `IControl.Paint` onto `Control.IControl.Paint` doesn't affect the re-implementation in `MyControl`, which maps `IControl.Paint` onto `MyControl.Paint`.

end example

Inherited public member declarations and inherited explicit interface member declarations participate in the interface mapping process for re-implemented interfaces.

Example:

```
C#  
  
interface IMethods  
{  
    void F();  
    void G();  
    void H();  
    void I();  
}  
  
class Base : IMethods  
{  
    void IMethods.F() {}  
    void IMethods.G() {}  
    public void H() {}  
    public void I() {}  
}  
  
class Derived : Base, IMethods  
{  
    public void F() {}  
    void IMethods.H() {}  
}
```

Here, the implementation of `IMethods` in `Derived` maps the interface methods onto `Derived.F`, `Base.IMethods.G`, `Derived.IMethods.H`, and `Base.I`.

end example

When a class implements an interface, it implicitly also implements all that interface's base interfaces. Likewise, a re-implementation of an interface is also implicitly a re-implementation of all of the interface's base interfaces.

Example:

```
C#  
  
interface IBase  
{  
    void F();  
}  
  
interface IDerived : IBase  
{
```

```

    void G();
}

class C : IDerived
{
    void IBase.F() {...}
    void IDerived.G() {...}
}

class D : C, IDerived
{
    public void F() {...}
    public void G() {...}
}

```

Here, the re-implementation of `IDerived` also re-implements `IBase`, mapping `IBase.F` onto `D.F`.

end example

17.6.8 Abstract classes and interfaces

Like a non-abstract class, an abstract class shall provide implementations of all members of the interfaces that are listed in the base class list of the class. However, an abstract class is permitted to map interface methods onto abstract methods.

Example:

```

C#

interface IMethods
{
    void F();
    void G();
}

abstract class C : IMethods
{
    public abstract void F();
    public abstract void G();
}

```

Here, the implementation of `IMethods` maps `F` and `G` onto abstract methods, which shall be overridden in non-abstract classes that derive from `C`.

end example

Explicit interface member implementations cannot be abstract, but explicit interface member implementations are of course permitted to call abstract methods.

Example:

```
C#  
  
interface IMethods  
{  
    void F();  
    void G();  
}  
  
abstract class C: IMethods  
{  
    void IMethods.F() { FF(); }  
    void IMethods.G() { GG(); }  
    protected abstract void FF();  
    protected abstract void GG();  
}
```

Here, non-abstract classes that derive from `C` would be required to override `FF` and `GG`, thus providing the actual implementation of `IMethods`.

end example

18 Enums

Article • 2023-01-12 • 6 minutes to read

18.1 General

An *enum type* is a distinct value type ([§8.3](#)) that declares a set of named constants.

Example: The example

```
C#  
  
enum Color  
{  
    Red,  
    Green,  
    Blue  
}
```

declares an enum type named `Color` with members `Red`, `Green`, and `Blue`.

end example

18.2 Enum declarations

An enum declaration declares a new enum type. An enum declaration begins with the keyword `enum`, and defines the name, accessibility, underlying type, and members of the enum.

ANTLR

```
enum_declaration  
  : attributes? enum_modifier* 'enum' identifier enum_base? enum_body ';'?  
  ;  
  
enum_base  
  : ':' integral_type  
  | ':' integral_type_name  
  ;  
  
integral_type_name  
  : type_name // Shall resolve to an integral type other than char  
  ;  
  
enum_body  
  : '{' enum_member_declarations? '}'
```

```
| '{' enum_member_declarations ',' '}'  
;
```

Each enum type has a corresponding integral type called the *underlying type* of the enum type. This underlying type shall be able to represent all the enumerator values defined in the enumeration. If the *enum_base* is present, it explicitly declares the underlying type. The underlying type shall be one of the *integral types* (§8.3.6) other than `char`. The underlying type may be specified either by an `integral_type` (§8.3.5), or an `integral_type_name`. The `integral_type_name` is resolved in the same way as `type_name` (§7.8.1), including taking any using directives (§13.5) into account.

Note: The `char` type cannot be used as an underlying type, either by keyword or via an `integral_type_name`. *end note*

An enum declaration that does not explicitly declare an underlying type has an underlying type of `int`.

Example: The example

```
C#  
  
enum Color : long  
{  
    Red,  
    Green,  
    Blue  
}
```

declares an enum with an underlying type of `long`.

end example

Note: A developer might choose to use an underlying type of `long`, as in the example, to enable the use of values that are in the range of `long` but not in the range of `int`, or to preserve this option for the future. *end note*

Note: C# allows a trailing comma in an *enum_body*, just like it allows one in an *array_initializer* (§16.7). *end note*

An enum declaration cannot include a type parameter list, but any enum nested inside a generic class declaration or a generic struct declaration is a generic enum declaration,

since type arguments for the containing type shall be supplied to create a constructed type (§8.4).

18.3 Enum modifiers

An *enum_declaration* may optionally include a sequence of enum modifiers:

ANTLR

```
enum_modifier
    : 'new'
    | 'public'
    | 'protected'
    | 'internal'
    | 'private'
    ;
```

It is a compile-time error for the same modifier to appear multiple times in an enum declaration.

The modifiers of an enum declaration have the same meaning as those of a class declaration (§14.2.2). However, the `abstract`, and `sealed`, and `static` modifiers are not permitted in an enum declaration. Enums cannot be abstract and do not permit derivation.

18.4 Enum members

The body of an enum type declaration defines zero or more enum members, which are the named constants of the enum type. No two enum members can have the same name.

ANTLR

```
enum_member_declarations
    : enum_member_declaration (',' enum_member_declaration)*
    ;
```

ANTLR

```
enum_member_declaration
    : attributes? identifier ('=' constant_expression)?
    ;
```

Each enum member has an associated constant value. The type of this value is the underlying type for the containing enum. The constant value for each enum member shall be in the range of the underlying type for the enum.

Example: The example

```
C#  
  
enum Color: uint  
{  
    Red = -1,  
    Green = -2,  
    Blue = -3  
}
```

results in a compile-time error because the constant values `-1`, `-2`, and `-3` are not in the range of the underlying integral type `uint`.

end example

Multiple enum members may share the same associated value.

Example: The example

```
C#  
  
enum Color  
{  
    Red,  
    Green,  
    Blue,  
    Max = Blue  
}
```

shows an enum in which two enum members—`Blue` and `Max`—have the same associated value.

end example

The associated value of an enum member is assigned either implicitly or explicitly. If the declaration of the enum member has a *constant_expression* initializer, the value of that constant expression, implicitly converted to the underlying type of the enum, is the associated value of the enum member. If the declaration of the enum member has no initializer, its associated value is set implicitly, as follows:

- If the enum member is the first enum member declared in the enum type, its associated value is zero.
- Otherwise, the associated value of the enum member is obtained by increasing the associated value of the textually preceding enum member by one. This increased value shall be within the range of values that can be represented by the underlying type, otherwise a compile-time error occurs.

Example: The example

```
C#  
  
enum Color  
{  
    Red,  
    Green = 10,  
    Blue  
}  
  
class Test  
{  
    static void Main()  
    {  
        Console.WriteLine(StringFromColor(Color.Red));  
        Console.WriteLine(StringFromColor(Color.Green));  
        Console.WriteLine(StringFromColor(Color.Blue));  
    }  
  
    static string StringFromColor(Color c)  
    {  
        switch (c)  
        {  
            case Color.Red:  
                return $"Red = {(int) c}";  
            case Color.Green:  
                return $"Green = {(int) c}";  
            case Color.Blue:  
                return $"Blue = {(int) c}";  
            default:  
                return "Invalid color";  
        }  
    }  
}
```

prints out the enum member names and their associated values. The output is:

```
Console  
  
Red = 0  
Green = 10  
Blue = 11
```

for the following reasons:

- the enum member `Red` is automatically assigned the value zero (since it has no initializer and is the first enum member);
- the enum member `Green` is explicitly given the value `10`;
- and the enum member `Blue` is automatically assigned the value one greater than the member that textually precedes it.

end example

The associated value of an enum member may not, directly or indirectly, use the value of its own associated enum member. Other than this circularity restriction, enum member initializers may freely refer to other enum member initializers, regardless of their textual position. Within an enum member initializer, values of other enum members are always treated as having the type of their underlying type, so that casts are not necessary when referring to other enum members.

Example: The example

```
C#  
  
enum Circular  
{  
    A = B,  
    B  
}
```

results in a compile-time error because the declarations of `A` and `B` are circular. `A` depends on `B` explicitly, and `B` depends on `A` implicitly.

end example

Enum members are named and scoped in a manner exactly analogous to fields within classes. The scope of an enum member is the body of its containing enum type. Within that scope, enum members can be referred to by their simple name. From all other code, the name of an enum member shall be qualified with the name of its enum type. Enum members do not have any declared accessibility—an enum member is accessible if its containing enum type is accessible.

18.5 The System.Enum type

The type `System.Enum` is the abstract base class of all enum types (this is distinct and different from the underlying type of the enum type), and the members inherited from `System.Enum` are available in any enum type. A boxing conversion (§10.2.9) exists from any enum type to `System.Enum`, and an unboxing conversion (§10.3.6) exists from `System.Enum` to any enum type.

Note that `System.Enum` is not itself an *enum_type*. Rather, it is a *class_type* from which all *enum_types* are derived. The type `System.Enum` inherits from the type `System.ValueType` (§8.3.2), which, in turn, inherits from type `object`. At run-time, a value of type `System.Enum` can be `null` or a reference to a boxed value of any enum type.

18.6 Enum values and operations

Each enum type defines a distinct type; an explicit enumeration conversion (§10.3.3) is required to convert between an enum type and an integral type, or between two enum types. The set of values of the enum type is the same as the set of values of the underlying type and is not restricted to the values of the named constants. Any value of the underlying type of an enum can be cast to the enum type, and is a distinct valid value of that enum type.

Enum members have the type of their containing enum type (except within other enum member initializers: see §18.4). The value of an enum member declared in enum type `E` with associated value `v` is `(E)v`.

The following operators can be used on values of enum types:

- `==`, `!=`, `<`, `>`, `<=`, `>=` (§11.11.6)
- binary `+` (§11.9.5)
- binary `-` (§11.9.6)
- `^`, `&`, `|` (§11.12.3)
- `~` (§11.8.5)
- `++`, `--` (§11.7.14 and §11.8.6)
- `sizeof` (§22.6.9)

Every enum type automatically derives from the class `System.Enum` (which, in turn, derives from `System.ValueType` and `object`). Thus, inherited methods and properties of this class can be used on values of an enum type.

19 Delegates

Article • 2023-01-12 • 13 minutes to read

19.1 General

A delegate declaration defines a class that is derived from the class `System.Delegate`. A delegate instance encapsulates an *invocation list*, which is a list of one or more methods, each of which is referred to as a *callable entity*. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Invoking a delegate instance with an appropriate set of arguments causes each of the delegate's callable entities to be invoked with the given set of arguments.

Note: An interesting and useful property of a delegate instance is that it does not know or care about the classes of the methods it encapsulates; all that matters is that those methods be compatible (§19.4) with the delegate's type. This makes delegates perfectly suited for "anonymous" invocation. *end note*

19.2 Delegate declarations

A *delegate_declaration* is a *type_declaration* (§13.7) that declares a new delegate type.

ANTLR

```
delegate_declaration
: attributes? delegate_modifier* 'delegate' return_type identifier
  variant_type_parameter_list? '(' formal_parameter_list? ')'
  type_parameter_constraints_clause* ';';
;

delegate_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| unsafe_modifier // unsafe code support
;

```

unsafe_modifier is defined in §22.2.

It is a compile-time error for the same modifier to appear multiple times in a delegate declaration.

A delegate declaration shall not supply any *type_parameter_constraints_clauses* unless it also supplies a *variant_type_parameter_list*.

A delegate declaration that supplies a *variant_type_parameter_list* is a generic delegate declaration. Additionally, any delegate nested inside a generic class declaration or a generic struct declaration is itself a generic delegate declaration, since type arguments for the containing type shall be supplied to create a constructed type (§8.4).

The `new` modifier is only permitted on delegates declared within another type, in which case it specifies that such a delegate hides an inherited member by the same name, as described in §14.3.5.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the delegate type. Depending on the context in which the delegate declaration occurs, some of these modifiers might not be permitted (§7.5.2).

The delegate's type name is *identifier*.

The optional *formal_parameter_list* specifies the parameters of the delegate, and *return_type* indicates the return type of the delegate.

The optional *variant_type_parameter_list* (§17.2.3) specifies the type parameters to the delegate itself.

The return type of a delegate type shall be either `void`, or output-safe (§17.2.3.2).

All the formal parameter types of a delegate type shall be input-safe (§17.2.3.2). In addition, any output or reference parameter types shall also be output-safe.

Note: Output parameters are required to be input-safe due to common implementation restrictions. *end note*

Furthermore, each class type constraint, interface type constraint and type parameter constraint on any type parameters of the delegate shall be input-safe.

Delegate types in C# are name equivalent, not structurally equivalent.

Example:

```
C#  
  
delegate int D1(int i, double d);  
delegate int D2(int c, double d);
```

The delegate types `D1` and `D2` are two different types, so they are not interchangeable, despite their identical signatures.

end example

Like other generic type declarations, type arguments shall be given to create a constructed delegate type. The parameter types and return type of a constructed delegate type are created by substituting, for each type parameter in the delegate declaration, the corresponding type argument of the constructed delegate type.

The only way to declare a delegate type is via a *delegate_declaration*. Every delegate type is a reference type that is derived from `System.Delegate`. The members required for every delegate type are detailed in §19.3. Delegate types are implicitly `sealed`, so it is not permissible to derive any type from a delegate type. It is also not permissible to declare a non-delegate class type deriving from `System.Delegate`. `System.Delegate` is not itself a delegate type; it is a class type from which all delegate types are derived.

19.3 Delegate members

Every delegate type inherits members from the `Delegate` class as described in §14.3.4. In addition, every delegate type must provide a non-generic `Invoke` method whose parameter list matches the *formal_parameter_list* in the delegate declaration, and whose return type matches the *return_type* in the delegate declaration. The `Invoke` method shall be at least as accessible as the containing delegate type. Calling the `Invoke` method on a delegate type is semantically equivalent to using the delegate invocation syntax (§19.6).

Implementations may define additional members in the delegate type.

Except for instantiation, any operation that can be applied to a class or class instance can also be applied to a delegate class or instance, respectively. In particular, it is possible to access members of the `System.Delegate` type via the usual member access syntax.

19.4 Delegate compatibility

A method or delegate type `M` is *compatible* with a delegate type `D` if all of the following are true:

- `D` and `M` have the same number of parameters, and each parameter in `D` has the same `ref` or `out` modifiers as the corresponding parameter in `M`.
- For each value parameter (a parameter with no `ref` or `out` modifier), an identity conversion (§10.2.2) or implicit reference conversion (§10.2.8) exists from the parameter type in `D` to the corresponding parameter type in `M`.
- For each `ref` or `out` parameter, the parameter type in `D` is the same as the parameter type in `M`.
- An identity or implicit reference conversion exists from the return type of `M` to the return type of `D`.

This definition of consistency allows covariance in return type and contravariance in parameter types.

Example:

```
C#
delegate int D1(int i, double d);
delegate int D2(int c, double d);
delegate object D3(string s);

class A
{
    public static int M1(int a, double b) {...}
}

class B
{
    public static int M1(int f, double g) {...}
    public static void M2(int k, double l) {...}
    public static int M3(int g) {...}
    public static void M4(int g) {...}
    public static object M5(string s) {...}
    public static int[] M6(object o) {...}
}
```

The methods `A.M1` and `B.M1` are compatible with both the delegate types `D1` and `D2`, since they have the same return type and parameter list. The methods `B.M2`, `B.M3`, and `B.M4` are incompatible with the delegate types `D1` and `D2`, since they have different return types or parameter lists. The methods `B.M5` and `B.M6` are both compatible with delegate type `D3`.

end example

Example:

C#

```
delegate bool Predicate<T>(T value);

class X
{
    static bool F(int i) {...}
    static bool G(string s) {...}
}
```

The method `X.F` is compatible with the delegate type `Predicate<int>` and the method `X.G` is compatible with the delegate type `Predicate<string>`.

end example

Note: The intuitive meaning of delegate compatibility is that a method is compatible with a delegate type if every invocation of the delegate could be replaced with an invocation of the method without violating type safety, treating optional parameters and parameter arrays as explicit parameters. For example, in the following code:

C#

```
delegate void Action<T>(T arg);

class Test
{
    static void Print(object value) => Console.WriteLine(value);

    static void Main()
    {
        Action<string> log = Print;
        log("text");
    }
}
```

The `Print` method is compatible with the `Action<string>` delegate type because any invocation of an `Action<string>` delegate would also be a valid invocation of the `Print` method.

If the signature of the `Print` method above were changed to `Print(object value, bool prependTimestamp = false)` for example, the `Print` method would no longer be compatible with `Action<string>` by the rules of this clause.

end note

19.5 Delegate instantiation

An instance of a delegate is created by a *delegate_creation_expression* (§11.7.15.6), a conversion to a delegate type, delegate combination or delegate removal. The newly created delegate instance then refers to one or more of:

- The static method referenced in the *delegate_creation_expression*, or
- The target object (which cannot be `null`) and instance method referenced in the *delegate_creation_expression*, or
- Another delegate (§11.7.15.6).

Example:

```
C#  
  
delegate void D(int x);  
  
class C  
{  
    public static void M1(int i) {...}  
    public void M2(int i) {...}  
}  
  
class Test  
{  
    static void Main()  
    {  
        D cd1 = new D(C.M1); // Static method  
        C t = new C();  
        D cd2 = new D(t.M2); // Instance method  
        D cd3 = new D(cd2); // Another delegate  
    }  
}
```

end example

The set of methods encapsulated by a delegate instance is called an *invocation list*. When a delegate instance is created from a single method, it encapsulates that method, and its invocation list contains only one entry. However, when two non-`null` delegate instances are combined, their invocation lists are concatenated—in the order left operand then right operand—to form a new invocation list, which contains two or more entries.

When a new delegate is created from a single delegate the resultant invocation list has just one entry, which is the source delegate (§11.7.15.6).

Delegates are combined using the binary `+` (§11.9.5) and `+=` operators (§11.19.3). A delegate can be removed from a combination of delegates, using the binary `-` (§11.9.6) and `-=` operators (§11.19.3). Delegates can be compared for equality (§11.11.9).

Example: The following example shows the instantiation of a number of delegates, and their corresponding invocation lists:

```
C#

delegate void D(int x);

class C
{
    public static void M1(int i) {...}
    public static void M2(int i) {...}
}

class Test
{
    static void Main()
    {
        D cd1 = new D(C.M1); // M1 - one entry in invocation list
        D cd2 = new D(C.M2); // M2 - one entry
        D cd3 = cd1 + cd2;   // M1 + M2 - two entries
        D cd4 = cd3 + cd1;   // M1 + M2 + M1 - three entries
        D cd5 = cd4 + cd3;   // M1 + M2 + M1 + M1 + M2 - five entries
        D td3 = new D(cd3);  // [M1 + M2] - ONE entry in invocation
                            // list, which is itself a list of two
                            // methods.
        D td4 = td3 + cd1;   // [M1 + M2] + M1 - two entries
        D cd6 = cd4 - cd2;   // M1 + M1 - two entries in invocation list
        D td6 = td4 - cd2;   // [M1 + M2] + M1 - two entries in
                            // invocation list,
                            // but still three methods called, M2 not
                            // removed.
    }
}
```

When `cd1` and `cd2` are instantiated, they each encapsulate one method. When `cd3` is instantiated, it has an invocation list of two methods, `M1` and `M2`, in that order. `cd4`'s invocation list contains `M1`, `M2`, and `M1`, in that order. For `cd5`, the invocation list contains `M1`, `M2`, `M1`, `M1`, and `M2`, in that order.

When `cd1` and `cd2` are instantiated, they each encapsulate one method.

When `cd3` is instantiated, it has an invocation list of two methods, `M1` and `M2`, in that order. `cd4`'s invocation list contains `M1`, `M2`, and `M1`, in that order. For `cd5` the invocation list contains `M1`, `M2`, `M1`, `M1`, and `M2`, in that order.

When creating a delegate from another delegate with a *delegate_creation_expression* the result has an invocation list with a different structure from the original, but which results in the same methods being invoked in the same order. When `td3` is created from `cd3` its invocation list has just one member, but that member is a list of the methods `M1` and `M2` and those methods are invoked by `td3` in the same order as they are invoked by `cd3`. Similarly when `td4` is instantiated its invocation list has just two entries but it invokes the three methods `M1`, `M2`, and `M1`, in that order just as `cd4` does.

The structure of the invocation list affects delegate subtraction. Delegate `cd6`, created by subtracting `cd2` (which invokes `M2`) from `cd4` (which invokes `M1`, `M2`, and `M1`) invokes `M1` and `M1`. However delegate `td6`, created by subtracting `cd2` (which invokes `M2`) from `td4` (which invokes `M1`, `M2`, and `M1`) still invokes `M1`, `M2` and `M1`, in that order, as `M2` is not a single entry in the list but a member of a nested list. For more examples of combining (as well as removing) delegates, see [§19.6](#).

end example

Once instantiated, a delegate instance always refers to the same invocation list.

Note: Remember, when two delegates are combined, or one is removed from another, a new delegate results with its own invocation list; the invocation lists of the delegates combined or removed remain unchanged. *end note*

19.6 Delegate invocation

C# provides special syntax for invoking a delegate. When a non-`null` delegate instance whose invocation list contains one entry, is invoked, it invokes the one method with the same arguments it was given, and returns the same value as the referred to method. (See [§11.7.8.4](#) for detailed information on delegate invocation.) If an exception occurs during the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, as if that method had directly called the method to which that delegate referred.

Invocation of a delegate instance whose invocation list contains multiple entries, proceeds by invoking each of the methods in the invocation list, synchronously, in order. Each method so called is passed the same set of arguments as was given to the delegate instance. If such a delegate invocation includes reference parameters ([§14.6.2.3](#)), each method invocation will occur with a reference to the same variable;

changes to that variable by one method in the invocation list will be visible to methods further down the invocation list. If the delegate invocation includes output parameters or a return value, their final value will come from the invocation of the last delegate in the list. If an exception occurs during processing of the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, and any methods further down the invocation list are not invoked.

Attempting to invoke a delegate instance whose value is `null` results in an exception of type `System.NullReferenceException`.

Example: The following example shows how to instantiate, combine, remove, and invoke delegates:

```
C#

delegate void D(int x);

class C
{
    public static void M1(int i) => Console.WriteLine("C.M1: " + i);

    public static void M2(int i) => Console.WriteLine("C.M2: " + i);

    public void M3(int i) => Console.WriteLine("C.M3: " + i);
}

class Test
{
    static void Main()
    {
        D cd1 = new D(C.M1);
        cd1(-1);           // call M1
        D cd2 = new D(C.M2);
        cd2(-2);           // call M2
        D cd3 = cd1 + cd2;
        cd3(10);           // call M1 then M2
        cd3 += cd1;
        cd3(20);           // call M1, M2, then M1
        C c = new C();
        D cd4 = new D(c.M3);
        cd3 += cd4;
        cd3(30);           // call M1, M2, M1, then M3
        cd3 -= cd1;        // remove last M1
        cd3(40);           // call M1, M2, then M3
        cd3 -= cd4;
        cd3(50);           // call M1 then M2
        cd3 -= cd2;
        cd3(60);           // call M1
        cd3 -= cd2;        // impossible removal is benign
    }
}
```

```

        cd3(60);           // call M1
        cd3 -= cd1;       // invocation list is empty so cd3 is null
        // cd3(70);       // System.NullReferenceException thrown
        cd3 -= cd1;       // impossible removal is benign
    }
}

```

As shown in the statement `cd3 += cd1;`, a delegate can be present in an invocation list multiple times. In this case, it is simply invoked once per occurrence. In an invocation list such as this, when that delegate is removed, the last occurrence in the invocation list is the one actually removed.

Immediately prior to the execution of the final statement, `cd3 -= cd1;`, the delegate `cd3` refers to an empty invocation list. Attempting to remove a delegate from an empty list (or to remove a non-existent delegate from a non-empty list) is not an error.

The output produced is:

Console

```

C.M1: -1
C.M2: -2
C.M1: 10
C.M2: 10
C.M1: 20
C.M2: 20
C.M1: 20
C.M1: 30
C.M2: 30
C.M1: 30
C.M3: 30
C.M1: 40
C.M2: 40
C.M3: 40
C.M1: 50
C.M2: 50
C.M1: 60
C.M1: 60

```

end example

20 Exceptions

Article • 2022-03-29 • 3 minutes to read

20.1 General

Exceptions in C# provide a structured, uniform, and type-safe way of handling both system level and application-level error conditions.

20.2 Causes of exceptions

Exception can be thrown in two different ways.

- A `throw` statement (§12.10.6) throws an exception immediately and unconditionally. Control never reaches the statement immediately following the `throw`.
- Certain exceptional conditions that arise during the processing of C# statements and expression cause an exception in certain circumstances when the operation cannot be completed normally. See §20.5 for a list of the various exceptions that can occur in this way.

Example: An integer division operation (§11.9.3) throws a `System.DivideByZeroException` if the denominator is zero. end example

20.3 The System.Exception class

The `System.Exception` class is the base type of all exceptions. This class has a few notable properties that all exceptions share:

- `Message` is a read-only property of type `string` that contains a human-readable description of the reason for the exception.
- `InnerException` is a read-only property of type `Exception`. If its value is non-`null`, it refers to the exception that caused the current exception. (That is, the current exception was raised in a catch block handling the `InnerException`.) Otherwise, its value is `null`, indicating that this exception was not caused by another exception. The number of exception objects chained together in this manner can be arbitrary.

The value of these properties can be specified in calls to the instance constructor for `System.Exception`.

20.4 How exceptions are handled

Exceptions are handled by a `try` statement (§12.11).

When an exception occurs, the system searches for the nearest catch clause that can handle the exception, as determined by the run-time type of the exception. First, the current method is searched for a lexically enclosing `try` statement, and the associated `catch` clauses of the `try` statement are considered in order. If that fails, the method that called the current method is searched for a lexically enclosing `try` statement that encloses the point of the call to the current method. This search continues until a `catch` clause is found that can handle the current exception, by naming an exception class that is of the same class, or a base class, of the run-time type of the exception being thrown. A `catch` clause that doesn't name an exception class can handle any exception.

Once a matching `catch` clause is found, the system prepares to transfer control to the first statement of the `catch` clause. Before execution of the `catch` clause begins, the system first executes, in order, any `finally` clauses that were associated with `try` statements more nested than the one that caught the exception.

If no matching `catch` clause is found:

- If the search for a matching `catch` clause reaches a static constructor (§14.12) or static field initializer, then a `System.TypeInitializationException` is thrown at the point that triggered the invocation of the static constructor. The inner exception of the `System.TypeInitializationException` contains the exception that was originally thrown.
- Otherwise, if an exception occurs during finalizer execution, and that exception is not caught, then the behavior is unspecified.
- Otherwise, if the search for matching `catch` clauses reaches the code that initially started the thread, then execution of the thread is terminated. The impact of such termination is implementation-defined.

20.5 Common exception classes

The following exceptions are thrown by certain C# operations.

Exception Type	Description
<code>System.ArithmeticException</code>	A base class for exceptions that occur during arithmetic operations, such as <code>System.DivideByZeroException</code> and <code>System.OverflowException</code> .

Exception Type	Description
<code>System.ArrayTypeMismatchException</code>	Thrown when a store into an array fails because the type of the stored element is incompatible with the type of the array.
<code>System.DivideByZeroException</code>	Thrown when an attempt to divide an integral value by zero occurs.
<code>System.IndexOutOfRangeException</code>	Thrown when an attempt to index an array via an index that is less than zero or outside the bounds of the array.
<code>System.InvalidCastException</code>	Thrown when an explicit conversion from a base type or interface to a derived type fails at run-time.
<code>System.NullReferenceException</code>	Thrown when a <code>null</code> reference is used in a way that causes the referenced object to be required.
<code>System.OutOfMemoryException</code>	Thrown when an attempt to allocate memory (via <code>new</code>) fails.
<code>System.OverflowException</code>	Thrown when an arithmetic operation in a <code>checked</code> context overflows.
<code>System.StackOverflowException</code>	Thrown when the execution stack is exhausted by having too many pending calls; typically indicative of very deep or unbounded recursion.
<code>System.TypeInitializationException</code>	Thrown when a static constructor or static field initializer throws an exception, and no <code>catch</code> clause exists to catch it.

21 Attributes

Article • 2023-01-12 • 26 minutes to read

21.1 General

Much of the C# language enables the programmer to specify declarative information about the entities defined in the program. For example, the accessibility of a method in a class is specified by decorating it with the *method_modifiers* `public`, `protected`, `internal`, and `private`.

C# enables programmers to invent new kinds of declarative information, called **attributes**. Programmers can then attach attributes to various program entities, and retrieve attribute information in a run-time environment.

Note: For instance, a framework might define a `HelpAttribute` attribute that can be placed on certain program elements (such as classes and methods) to provide a mapping from those program elements to their documentation. *end note*

Attributes are defined through the declaration of attribute classes (§21.2), which can have positional and named parameters (§21.2.3). Attributes are attached to entities in a C# program using attribute specifications (§21.3), and can be retrieved at run-time as attribute instances (§21.4).

21.2 Attribute classes

21.2.1 General

A class that derives from the abstract class `System.Attribute`, whether directly or indirectly, is an **attribute class**. The declaration of an attribute class defines a new kind of attribute that can be placed on program entities. By convention, attribute classes are named with a suffix of `Attribute`. Uses of an attribute may either include or omit this suffix.

A generic class declaration shall not use `System.Attribute` as a direct or indirect base class.

Example:

```
C#
```

```
public class B : Attribute {}
public class C<T> : B {} // Error - generic cannot be an attribute
```

end example

21.2.2 Attribute usage

The attribute `AttributeUsage` (§21.5.2) is used to describe how an attribute class can be used.

`AttributeUsage` has a positional parameter (§21.2.3) that enables an attribute class to specify the kinds of program entities on which it can be used.

Example: The following example defines an attribute class named `SimpleAttribute` that can be placed on *class_declarations* and *interface_declarations* only, and shows several uses of the `Simple` attribute.

```
C#

[AttributeUsage(AttributeTargets.Class | AttributeTargets.Interface)]
public class SimpleAttribute : Attribute
{
    ...
}

[Simple] class Class1 {...}
[Simple] interface Interface1 {...}
```

Although this attribute is defined with the name `SimpleAttribute`, when this attribute is used, the `Attribute` suffix may be omitted, resulting in the short name `Simple`. Thus, the example above is semantically equivalent to the following

```
C#

[SimpleAttribute] class Class1 {...}
[SimpleAttribute] interface Interface1 {...}
```

end example

`AttributeUsage` has a named parameter (§21.2.3), called `AllowMultiple`, which indicates whether the attribute can be specified more than once for a given entity. If

`AllowMultiple` for an attribute class is true, then that attribute class is a **multi-use attribute class**, and can be specified more than once on an entity. If `AllowMultiple` for

an attribute class is false or it is unspecified, then that attribute class is a *single-use attribute class*, and can be specified at most once on an entity.

Example: The following example defines a multi-use attribute class named `AuthorAttribute` and shows a class declaration with two uses of the `Author` attribute:

```
C#

[AttributeUsage(AttributeTargets.Class, AllowMultiple = true)]
public class AuthorAttribute : Attribute
{
    public string Name { get; }
    public AuthorAttribute(string name) => Name = name;
}

[Author("Brian Kernighan"), Author("Dennis Ritchie")]
class Class1
{
    ...
}
```

end example

`AttributeUsage` has another named parameter (§21.2.3), called `Inherited`, which indicates whether the attribute, when specified on a base class, is also inherited by classes that derive from that base class. If `Inherited` for an attribute class is true, then that attribute is inherited. If `Inherited` for an attribute class is false then that attribute is not inherited. If it is unspecified, its default value is true.

An attribute class `X` not having an `AttributeUsage` attribute attached to it, as in

```
C#

class X : Attribute { ... }
```

is equivalent to the following:

```
C#

[AttributeUsage(
    AttributeTargets.All,
    AllowMultiple = false,
    Inherited = true)
]
class X : Attribute { ... }
```

21.2.3 Positional and named parameters

Attribute classes can have *positional parameters* and *named parameters*. Each public instance constructor for an attribute class defines a valid sequence of positional parameters for that attribute class. Each non-static public read-write field and property for an attribute class defines a named parameter for the attribute class. For a property to define a named parameter, that property shall have both a public get accessor and a public set accessor.

Example: The following example defines an attribute class named `HelpAttribute` that has one positional parameter, `url`, and one named parameter, `Topic`. Although it is non-static and public, the property `Url` does not define a named parameter, since it is not read-write. Two uses of this attribute are also shown:

```
C#

[AttributeUsage(AttributeTargets.Class)]
public class HelpAttribute : Attribute
{
    public HelpAttribute(string url) // url is a positional parameter
    {
        ...
    }

    // Topic is a named parameter
    public string Topic
    {
        get;
        set;
    }

    public string Url { get; }
}

[Help("http://www.mycompany.com/xxx/Class1.htm")]
class Class1
{
}

[Help("http://www.mycompany.com/xxx/Misc.htm", Topic = "Class2")]
class Class2
{
}
```

end example

21.2.4 Attribute parameter types

The types of positional and named parameters for an attribute class are limited to the *attribute parameter types*, which are:

- One of the following types: `bool`, `byte`, `char`, `double`, `float`, `int`, `long`, `sbyte`, `short`, `string`, `uint`, `ulong`, `ushort`.
- The type `object`.
- The type `System.Type`.
- Enum types.
- Single-dimensional arrays of the above types.
- A constructor argument or public field that does not have one of these types, shall not be used as a positional or named parameter in an attribute specification.

21.3 Attribute specification

Attribute specification is the application of a previously defined attribute to a program entity. An attribute is a piece of additional declarative information that is specified for a program entity. Attributes can be specified at global scope (to specify attributes on the containing assembly or module) and for *type_declarations* (§13.7), *class_member_declarations* (§14.3), *interface_member_declarations* (§17.4), *struct_member_declarations* (§15.3), *enum_member_declarations* (§18.2), *accessor_declarations* (§14.7.3), *event_accessor_declarations* (§14.8), elements of *formal_parameter_lists* (§14.6.2), and elements of *type_parameter_lists* (§14.2.3).

Attributes are specified in *attribute sections*. An attribute section consists of a pair of square brackets, which surround a comma-separated list of one or more attributes. The order in which attributes are specified in such a list, and the order in which sections attached to the same program entity are arranged, is not significant. For instance, the attribute specifications `[A][B]`, `[B][A]`, `[A, B]`, and `[B, A]` are equivalent.

ANTLR

```
global_attributes
    : global_attribute_section+
    ;

global_attribute_section
    : '[' global_attribute_target_specifier attribute_list ']'
    | '[' global_attribute_target_specifier attribute_list ',' ']'
    ;

global_attribute_target_specifier
    : global_attribute_target ':'
    ;

global_attribute_target
```

```

: identifier
;

attributes
: attribute_section+
;

attribute_section
: '[' attribute_target_specifier? attribute_list ']'
| '[' attribute_target_specifier? attribute_list ',' ']'
;

attribute_target_specifier
: attribute_target ':'
;

attribute_target
: identifier
| keyword
;

attribute_list
: attribute (',' attribute)*
;

attribute

;

named_argument
: identifier '=' attribute_argument_expression
;

```

```
attribute_argument_expression
```

```
  : expression
```

```
  ;
```

For the production *global_attribute_target*, and in the text below, *identifier* shall have a spelling equal to `assembly` or `module`, where equality is that defined in §6.4.3. For the production *attribute_target*, and in the text below, *identifier* shall have a spelling that is not equal to `assembly` or `module`, using the same definition of equality as above.

An attribute consists of an *attribute_name* and an optional list of positional and named arguments. The positional arguments (if any) precede the named arguments. A positional argument consists of an *attribute_argument_expression*; a named argument consists of a name, followed by an equal sign, followed by an *attribute_argument_expression*, which, together, are constrained by the same rules as simple assignment. The order of named arguments is not significant.

Note: For convenience, a trailing comma is allowed in a *global_attribute_section* and an *attribute_section*, just as one is allowed in an *array_initializer* (§16.7).

The *attribute_name* identifies an attribute class.

When an attribute is placed at the global level, a *global_attribute_target_specifier* is required. When the *global_attribute_target* is equal to:

- `assembly` — the target is the containing assembly
- `module` — the target is the containing module

No other values for *global_attribute_target* are allowed.

The standardized *attribute_target* names are `event`, `field`, `method`, `param`, `property`, `return`, `type`, and `typevar`. These target names shall only be used in the following contexts:

- `event` — an event.
- `field` — a field. A field-like event (i.e., one without accessors) (§14.8.2) and an automatically implemented property (§14.7.4) can also have an attribute with this target.
- `method` — a constructor, finalizer, method, operator, property get and set accessors, indexer get and set accessors, and event add and remove accessors. A field-like event (i.e., one without accessors) can also have an attribute with this target.

- `param` — a property set accessor, an indexer set accessor, event add and remove accessors, and a parameter in a constructor, method, and operator.
- `property` — a property and an indexer.
- `return` — a delegate, method, operator, property get accessor, and indexer get accessor.
- `type` — a delegate, class, struct, enum, and interface.
- `typevar` — a type parameter.

Certain contexts permit the specification of an attribute on more than one target. A program can explicitly specify the target by including an *attribute_target_specifier*. Without an *attribute_target_specifier* a default is applied, but an *attribute_target_specifier* can be used to affirm or override the default. The contexts are resolved as follows:

- For an attribute on a delegate declaration the default target is the delegate. Otherwise when the *attribute_target* is equal to:
 - `type` — the target is the delegate
 - `return` — the target is the return value
- For an attribute on a method declaration the default target is the method. Otherwise when the *attribute_target* is equal to:
 - `method` — the target is the method
 - `return` — the target is the return value
- For an attribute on an operator declaration the default target is the operator. Otherwise when the *attribute_target* is equal to:
 - `method` — the target is the operator
 - `return` — the target is the return value
- For an attribute on a get accessor declaration for a property or indexer declaration the default target is the associated method. Otherwise when the *attribute_target* is equal to:
 - `method` — the target is the associated method
 - `return` — the target is the return value
- For an attribute specified on a set accessor for a property or indexer declaration the default target is the associated method. Otherwise when the *attribute_target* is equal to:
 - `method` — the target is the associated method
 - `param` — the target is the lone implicit parameter
- For an attribute on an automatically implemented property declaration the default target is the property. Otherwise when the *attribute_target* is equal to:
 - `field` — the target is the compiler-generated backing field for the property
- For an attribute specified on an event declaration that omits *event_accessor_declarations* the default target is the event declaration. Otherwise

when the *attribute_target* is equal to:

- `event` — the target is the event declaration
- `field` — the target is the field
- `method` — the targets are the methods
- In the case of an event declaration that does not omit *event_accessor_declarations* the default target is the method.
 - `method` — the target is the associated method
 - `param` — the target is the lone parameter

In all other contexts, inclusion of an *attribute_target_specifier* is permitted but unnecessary.

Example: a class declaration may either include or omit the specifier `type:`

```
C#  
  
[type: Author("Brian Kernighan")]  
class Class1 {}  
  
[Author("Dennis Ritchie")]  
class Class2 {}
```

end example.

An implementation can accept other *attribute_targets*, the purposes of which are implementation defined. An implementation that does not recognize such an *attribute_target* shall issue a warning and ignore the containing *attribute_section*.

By convention, attribute classes are named with a suffix of `Attribute`. An *attribute_name* can either include or omit this suffix. Specifically, an *attribute_name* is resolved as follows:

- If the right-most identifier of the *attribute_name* is a verbatim identifier (§6.4.3), then the *attribute_name* is resolved as a *type_name* (§7.8). If the result is not a type derived from `System.Attribute`, a compile-time error occurs.
- Otherwise,
 - The *attribute_name* is resolved as a *type_name* (§7.8) except any errors are suppressed. If this resolution is successful and results in a type derived from `System.Attribute` then the type is the result of this step.
 - The characters `Attribute` are appended to the right-most identifier in the *attribute_name* and the resulting string of tokens is resolved as a *type_name* (§7.8) except any errors are suppressed. If this resolution is successful and

results in a type derived from `System.Attribute` then the type is the result of this step.

If exactly one of the two steps above results in a type derived from `System.Attribute`, then that type is the result of the *attribute_name*. Otherwise a compile-time error occurs.

Example: If an attribute class is found both with and without this suffix, an ambiguity is present, and a compile-time error results. If the *attribute_name* is spelled such that its right-most *identifier* is a verbatim identifier (§6.4.3), then only an attribute without a suffix is matched, thus enabling such an ambiguity to be resolved. The example

```
C#

[AttributeUsage(AttributeTargets.All)]
public class Example : Attribute
{}

[AttributeUsage(AttributeTargets.All)]
public class ExampleAttribute : Attribute
{}

[Example]           // Error: ambiguity
class Class1 {}

[ExampleAttribute] // Refers to ExampleAttribute
class Class2 {}

[@Example]         // Refers to Example
class Class3 {}

[@ExampleAttribute] // Refers to ExampleAttribute
class Class4 {}
```

shows two attribute classes named `Example` and `ExampleAttribute`. The attribute `[Example]` is ambiguous, since it could refer to either `Example` or `ExampleAttribute`. Using a verbatim identifier allows the exact intent to be specified in such rare cases. The attribute `[ExampleAttribute]` is not ambiguous (although it would be if there was an attribute class named `ExampleAttributeAttribute!`). If the declaration for class `Example` is removed, then both attributes refer to the attribute class named `ExampleAttribute`, as follows:

```
C#

[AttributeUsage(AttributeTargets.All)]
public class ExampleAttribute : Attribute
{}
```

```

[Example]           // Refers to ExampleAttribute
class Class1 {}

[ExampleAttribute] // Refers to ExampleAttribute
class Class2 {}

[@Example]         // Error: no attribute named "Example"
class Class3 {}

```

end example

It is a compile-time error to use a single-use attribute class more than once on the same entity.

Example: The example

```

C#

[AttributeUsage(AttributeTargets.Class)]
public class HelpStringAttribute : Attribute
{
    public HelpStringAttribute(string value)
    {
        Value = value;
    }

    public string Value { get; }
}
[HelpString("Description of Class1")]
[HelpString("Another description of Class1")] // multiple uses not
allowed
public class Class1 {}

```

results in a compile-time error because it attempts to use `HelpString`, which is a single-use attribute class, more than once on the declaration of `Class1`.

end example

An expression `E` is an *attribute_argument_expression* if all of the following statements are true:

- The type of `E` is an attribute parameter type (§21.2.4).
- At compile-time, the value of `E` can be resolved to one of the following:
 - A constant value.

- A `System.Type` object obtained using a *typeof_expression* (§11.7.16) specifying a non-generic type, a closed constructed type (§8.4.3), or an unbound generic type (§8.4.4), but not an open type (§8.4.3).
- A single-dimensional array of *attribute_argument_expressions*.

Example:

```
C#
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Field)]
public class TestAttribute : Attribute
{
    public int P1 { get; set; }

    public Type P2 { get; set; }

    public object P3 { get; set; }
}

[Test(P1 = 1234, P3 = new int[]{1, 3, 5}, P2 = typeof(float))]
class MyClass {}

class C<T> {
    [Test(P2 = typeof(T))] // Error - T not a closed type.
    int x1;

    [Test(P2 = typeof(C<T>))] // Error - C<T>; not a closed type.
    int x2;

    [Test(P2 = typeof(C<int>))] // Ok
    int x3;

    [Test(P2 = typeof(C<>))] // Ok
    int x4;
}
```

end example

The attributes of a type declared in multiple parts are determined by combining, in an unspecified order, the attributes of each of its parts. If the same attribute is placed on multiple parts, it is equivalent to specifying that attribute multiple times on the type.

Example: The two parts:

```
C#
[Attr1, Attr2("hello")]
partial class A {}
```

```
[Attr3, Attr2("goodbye")]  
partial class A {}
```

are equivalent to the following single declaration:

```
C#  
  
[Attr1, Attr2("hello"), Attr3, Attr2("goodbye")]  
class A {}
```

end example

Attributes on type parameters combine in the same way.

21.4 Attribute instances

21.4.1 General

An *attribute instance* is an instance that represents an attribute at run-time. An attribute is defined with an attribute class, positional arguments, and named arguments. An attribute instance is an instance of the attribute class that is initialized with the positional and named arguments.

Retrieval of an attribute instance involves both compile-time and run-time processing, as described in the following subclasses.

21.4.2 Compilation of an attribute

The compilation of an *attribute* with attribute class T , *positional_argument_list* P , *named_argument_list* N , and specified on a program entity E is compiled into an assembly A via the following steps:

- Follow the compile-time processing steps for compiling an *object_creation_expression* of the form `new T(P)`. These steps either result in a compile-time error, or determine an instance constructor C on T that can be invoked at run-time.
- If C does not have public accessibility, then a compile-time error occurs.
- For each *named_argument* Arg in N :
 - Let $Name$ be the *identifier* of the *named_argument* Arg .

- `Name` shall identify a non-static read-write public field or property on `T`. If `T` has no such field or property, then a compile-time error occurs.
- If any of the values within *positional_argument_list* `P` or one of the values within *named_argument_list* `N` is of type `System.String` and the value is not well-formed as defined by the Unicode Standard, it is implementation-defined whether the value compiled is equal to the run-time value retrieved (§21.4.3).

Note: As an example, a string which contains a high surrogate UTF-16 code unit which isn't immediately followed by a low surrogate code unit is not well-formed. *end note*

- Store the following information (for run-time instantiation of the attribute) in the assembly output by the compiler as a result of compiling the program containing the attribute: the attribute class `T`, the instance constructor `C` on `T`, the *positional_argument_list* `P`, the *named_argument_list* `N`, and the associated program entity `E`, with the values resolved completely at compile-time.

21.4.3 Run-time retrieval of an attribute instance

The attribute instance represented by `T`, `C`, `P`, and `N`, and associated with `E` can be retrieved at run-time from the assembly `A` using the following steps:

- Follow the run-time processing steps for executing an *object_creation_expression* of the form `new T(P)`, using the instance constructor `C` and values as determined at compile-time. These steps either result in an exception, or produce an instance `O` of `T`.
- For each *named_argument* `Arg` in `N`, in order:
 - Let `Name` be the *identifier* of the *named_argument* `Arg`. If `Name` does not identify a non-static public read-write field or property on `O`, then an exception is thrown.
 - Let `Value` be the result of evaluating the *attribute_argument_expression* of `Arg`.
 - If `Name` identifies a field on `O`, then set this field to `Value`.
 - Otherwise, `Name` identifies a property on `O`. Set this property to `Value`.
 - The result is `O`, an instance of the attribute class `T` that has been initialized with the *positional_argument_list* `P` and the *named_argument_list* `N`.

Note: The format for storing `T`, `C`, `P`, `N` (and associating it with `E`) in `A` and the mechanism to specify `E` and retrieve `T`, `C`, `P`, `N` from `A` (and hence how an

attribute instance is obtained at runtime) is beyond the scope of this standard. *end note*

Example: In an implementation of the CLI, the `Help` attribute instances in the assembly created by compiling the example program in §21.2.3 can be retrieved with the following program:

C#

```
public sealed class InterrogateHelpUrls
{
    public static void Main(string[] args)
    {
        Type helpType = typeof(HelpAttribute);
        string assemblyName = args[0];
        foreach (Type t in Assembly.Load(assemblyName).GetTypes())
        {
            Console.WriteLine($"Type : {t}");
            HelpAttribute[] helpers =
                (HelpAttribute[])t.GetCustomAttributes(helpType, false);
            for (int at = 0; at != helpers.Length; at++)
            {
                Console.WriteLine($"\\tUrl : {helpers[at].Url}");
            }
        }
    }
}
```

end example

21.5 Reserved attributes

21.5.1 General

A small number of attributes affect the language in some way. These attributes include:

- `System.AttributeUsageAttribute` (§21.5.2), which is used to describe the ways in which an attribute class can be used.
- `System.Diagnostics.ConditionalAttribute` (§21.5.3), is a multi-use attribute class which is used to define conditional methods and conditional attribute classes. This attribute indicates a condition by testing a conditional compilation symbol.
- `System.ObsoleteAttribute` (§21.5.4), which is used to mark a member as obsolete.
- `System.Runtime.CompilerServices.CallerLineNumberAttribute` (§21.5.5.2), `System.Runtime.CompilerServices.CallerFilePathAttribute` (§21.5.5.3), and

`System.Runtime.CompilerServices.CallerMemberNameAttribute` (§21.5.5.4), which are used to supply information about the calling context to optional parameters.

An execution environment may provide additional implementation-specific attributes that affect the execution of a C# program.

21.5.2 The `AttributeUsage` attribute

The attribute `AttributeUsage` is used to describe the manner in which the attribute class can be used.

A class that is decorated with the `AttributeUsage` attribute shall derive from `System.Attribute`, either directly or indirectly. Otherwise, a compile-time error occurs.

Note: For an example of using this attribute, see §21.2.2. *end note*

21.5.3 The `Conditional` attribute

21.5.3.1 General

The attribute `Conditional` enables the definition of *conditional methods* and *conditional attribute classes*.

21.5.3.2 Conditional methods

A method decorated with the `Conditional` attribute is a conditional method. Each conditional method is thus associated with the conditional compilation symbols declared in its `Conditional` attributes.

Example:

```
C#  
  
class Eg  
{  
    [Conditional("ALPHA")]  
    [Conditional("BETA")]  
    public static void M()  
    {  
        // ...  
    }  
}
```

declares `Eg.M` as a conditional method associated with the two conditional compilation symbols `ALPHA` and `BETA`.

end example

A call to a conditional method is included if one or more of its associated conditional compilation symbols is defined at the point of call, otherwise the call is omitted.

A conditional method is subject to the following restrictions:

- The conditional method shall be a method in a *class_declaration* or *struct_declaration*. A compile-time error occurs if the `Conditional` attribute is specified on a method in an interface declaration.
- The conditional method shall have a return type of `void`.
- The conditional method shall not be marked with the `override` modifier. A conditional method can be marked with the `virtual` modifier, however. Overrides of such a method are implicitly conditional, and shall not be explicitly marked with a `Conditional` attribute.
- The conditional method shall not be an implementation of an interface method. Otherwise, a compile-time error occurs.
- The parameters of the conditional method shall not have the `out` modifier.

In addition, a compile-time error occurs if a delegate is created from a conditional method.

Example: The example

```
C#  
  
#define DEBUG  
using System;  
using System.Diagnostics;  
  
class Class1  
{  
    [Conditional("DEBUG")]  
    public static void M()  
    {  
        Console.WriteLine("Executed Class1.M");  
    }  
}  
  
class Class2  
{  
    public static void Test()  
    {  
        Class1.M();  
    }  
}
```

```
}  
}
```

declares `Class1.M` as a conditional method. `Class2`'s `Test` method calls this method. Since the conditional compilation symbol `DEBUG` is defined, if `Class2.Test` is called, it will call `M`. If the symbol `DEBUG` had not been defined, then `Class2.Test` would not call `Class1.M`.

end example

It is important to understand that the inclusion or exclusion of a call to a conditional method is controlled by the conditional compilation symbols at the point of the call.

Example: In the following code

```
C#  
  
// File class1.cs:  
class Class1  
{  
    [Conditional("DEBUG")]  
    public static void F()  
    {  
        Console.WriteLine("Executed Class1.F");  
    }  
}  
  
// File class2.cs:  
#define DEBUG  
class Class2  
{  
    public static void G()  
    {  
        Class1.F(); // F is called  
    }  
}  
  
// File class3.cs:  
#undef DEBUG  
class Class3  
{  
    public static void H()  
    {  
        Class1.F(); // F is not called  
    }  
}
```

the classes `Class2` and `Class3` each contain calls to the conditional method `Class1.F`, which is conditional based on whether or not `DEBUG` is defined. Since this symbol is defined in the context of `Class2` but not `Class3`, the call to `F` in `Class2` is included, while the call to `F` in `Class3` is omitted.

end example

The use of conditional methods in an inheritance chain can be confusing. Calls made to a conditional method through `base`, of the form `base.M`, are subject to the normal conditional method call rules.

Example: In the following code

```
C#  
  
// File class1.cs  
class Class1  
{  
    [Conditional("DEBUG")]  
    public virtual void M() => Console.WriteLine("Class1.M executed");  
}  
  
// File class2.cs  
class Class2 : Class1  
{  
    public override void M()  
    {  
        Console.WriteLine("Class2.M executed");  
        base.M(); // base.M is not called!  
    }  
}  
  
// File class3.cs  
#define DEBUG  
class Class3  
{  
    public static void Test()  
    {  
        Class2 c = new Class2();  
        c.M(); // M is called  
    }  
}
```

`Class2` includes a call to the `M` defined in its base class. This call is omitted because the base method is conditional based on the presence of the symbol `DEBUG`, which is undefined. Thus, the method writes to the console "`Class2.M executed`" only. Judicious use of *pp_declarations* can eliminate such problems.

end example

21.5.3.3 Conditional attribute classes

An attribute class (§21.2) decorated with one or more `Conditional` attributes is a conditional attribute class. A conditional attribute class is thus associated with the conditional compilation symbols declared in its `Conditional` attributes.

Example:

```
C#  
  
[Conditional("ALPHA")]  
[Conditional("BETA")]  
public class TestAttribute : Attribute {}
```

declares `TestAttribute` as a conditional attribute class associated with the conditional compilations symbols `ALPHA` and `BETA`.

end example

Attribute specifications (§21.3) of a conditional attribute are included if one or more of its associated conditional compilation symbols is defined at the point of specification, otherwise the attribute specification is omitted.

It is important to note that the inclusion or exclusion of an attribute specification of a conditional attribute class is controlled by the conditional compilation symbols at the point of the specification.

Example: In the example

```
C#  
  
// File test.cs:  
[Conditional("DEBUG")]  
public class TestAttribute : Attribute {}  
  
// File class1.cs:  
#define DEBUG  
[Test] // TestAttribute is specified  
class Class1 {}  
  
// File class2.cs:  
#undef DEBUG  
[Test] // TestAttribute is not specified  
class Class2 {}
```

the classes `Class1` and `Class2` are each decorated with attribute `Test`, which is conditional based on whether or not `DEBUG` is defined. Since this symbol is defined in the context of `Class1` but not `Class2`, the specification of the `Test` attribute on `Class1` is included, while the specification of the `Test` attribute on `Class2` is omitted.

end example

21.5.4 The Obsolete attribute

The attribute `Obsolete` is used to mark types and members of types that should no longer be used.

If a program uses a type or member that is decorated with the `Obsolete` attribute, the compiler shall issue a warning or an error. Specifically, the compiler shall issue a warning if no error parameter is provided, or if the error parameter is provided and has the value `false`. The compiler shall issue an error if the error parameter is specified and has the value `true`.

Example: In the following code

```
C#  
  
[Obsolete("This class is obsolete; use class B instead")]  
class A  
{  
    public void F() {}  
}  
  
class B  
{  
    public void F() {}  
}  
  
class Test  
{  
    static void Main()  
    {  
        A a = new A(); // Warning  
        a.F();  
    }  
}
```

the class `A` is decorated with the `Obsolete` attribute. Each use of `A` in `Main` results in a warning that includes the specified message, "This class is obsolete; use class `B`

instead".

end example

21.5.5 Caller-info attributes

21.5.5.1 General

For purposes such as logging and reporting, it is sometimes useful for a function member to obtain certain compile-time information about the calling code. The caller-info attributes provide a way to pass such information transparently.

When an optional parameter is annotated with one of the caller-info attributes, omitting the corresponding argument in a call does not necessarily cause the default parameter value to be substituted. Instead, if the specified information about the calling context is available, that information will be passed as the argument value.

Example:

C#

...

```
public void Log(  
    [CallerLineNumber] int line = -1,  
    [CallerFilePath] string path = null,  
    [CallerMemberName] string name = null  
)  
{  
    Console.WriteLine((line < 0) ? "No line" : "Line "+ line);  
    Console.WriteLine((path == null) ? "No file path" : path);  
    Console.WriteLine((name == null) ? "No member name" : name);  
}
```

A call to `Log()` with no arguments would print the line number and file path of the call, as well as the name of the member within which the call occurred.

end example

Caller-info attributes can occur on optional parameters anywhere, including in delegate declarations. However, the specific caller-info attributes have restrictions on the types of the parameters they can attribute, so that there will always be an implicit conversion from a substituted value to the parameter type.

It is an error to have the same caller-info attribute on a parameter of both the defining and implementing part of a partial method declaration. Only caller-info attributes in the defining part are applied, whereas caller-info attributes occurring only in the implementing part are ignored.

Caller information does not affect overload resolution. As the attributed optional parameters are still omitted from the source code of the caller, overload resolution ignores those parameters in the same way it ignores other omitted optional parameters (§11.6.4).

Caller information is only substituted when a function is explicitly invoked in source code. Implicit invocations such as implicit parent constructor calls do not have a source location and will not substitute caller information. Also, calls that are dynamically bound will not substitute caller information. When a caller-info attributed parameter is omitted in such cases, the specified default value of the parameter is used instead.

One exception is query expressions. These are considered syntactic expansions, and if the calls they expand to omit optional parameters with caller-info attributes, caller information will be substituted. The location used is the location of the query clause which the call was generated from.

If more than one caller-info attribute is specified on a given parameter, they are preferred in the following order: `CallerLineNumber`, `CallerFilePath`, `CallerMemberName`.

21.5.5.2 The `CallerLineNumber` attribute

The `System.Runtime.CompilerServices.CallerLineNumberAttribute` is allowed on optional parameters when there is a standard implicit conversion (§10.4.2) from the constant value `int.MaxValue` to the parameter's type. This ensures that any non-negative line number up to that value can be passed without error.

If a function invocation from a location in source code omits an optional parameter with the `CallerLineNumberAttribute`, then a numeric literal representing that location's line number is used as an argument to the invocation instead of the default parameter value.

If the invocation spans multiple lines, the line chosen is implementation-dependent.

The line number may be affected by `#line` directives (§6.5.8).

21.5.5.3 The `CallerFilePath` attribute

The `System.Runtime.CompilerServices.CallerFilePathAttribute` is allowed on optional parameters when there is a standard implicit conversion (§10.4.2) from `string` to the parameter's type.

If a function invocation from a location in source code omits an optional parameter with the `CallerFilePathAttribute`, then a string literal representing that location's file path is used as an argument to the invocation instead of the default parameter value.

The format of the file path is implementation-dependent.

The file path may be affected by `#line` directives (§6.5.8).

21.5.5.4 The `CallerMemberName` attribute

The `System.Runtime.CompilerServices.CallerMemberNameAttribute` is allowed on optional parameters when there is a standard implicit conversion (§10.4.2) from `string` to the parameter's type.

If a function invocation from a location within the body of a function member or within an attribute applied to the function member itself or its return type, parameters or type parameters in source code omits an optional parameter with the `CallerMemberNameAttribute`, then a string literal representing the name of that member is used as an argument to the invocation instead of the default parameter value.

For invocations that occur within generic methods, only the method name itself is used, without the type parameter list.

For invocations that occur within explicit interface member implementations, only the method name itself is used, without the preceding interface qualification.

For invocations that occur within property or event accessors, the member name used is that of the property or event itself.

For invocations that occur within indexer accessors, the member name used is that supplied by an `IndexerNameAttribute` (§21.6) on the indexer member, if present, or the default name `Item` otherwise.

For invocations that occur within field or event initializers, the member name used is the name of the field or event being initialized.

For invocations that occur within declarations of instance constructors, static constructors, finalizers and operators the member name used is implementation-dependent.

21.6 Attributes for interoperation

For interoperation with other languages, an indexer may be implemented using indexed properties. If no `IndexerName` attribute is present for an indexer, then the name `Item` is used by default. The `IndexerName` attribute enables a developer to override this default and specify a different name.

Example: By default, an indexer's name is `Item`. This can be overridden, as follows:

C#

```
[System.Runtime.CompilerServices.IndexerName("TheItem")]
public int this[int index]
{
    get { ... }
    set { ... }
}
```

Now, the indexer's name is `TheItem`.

end example

22 Unsafe code

Article • 2023-01-17 • 36 minutes to read

22.1 General

An implementation that does not support unsafe code is required to diagnose any usage of the syntactic rules defined in this clause.

The remainder of this clause, including all of its subclauses, is conditionally normative.

Note: The core C# language, as defined in the preceding clauses, differs notably from C and C++ in its omission of pointers as a data type. Instead, C# provides references and the ability to create objects that are managed by a garbage collector. This design, coupled with other features, makes C# a much safer language than C or C++. In the core C# language, it is simply not possible to have an uninitialized variable, a “dangling” pointer, or an expression that indexes an array beyond its bounds. Whole categories of bugs that routinely plague C and C++ programs are thus eliminated.

While practically every pointer type construct in C or C++ has a reference type counterpart in C#, nonetheless, there are situations where access to pointer types becomes a necessity. For example, interfacing with the underlying operating system, accessing a memory-mapped device, or implementing a time-critical algorithm might not be possible or practical without access to pointers. To address this need, C# provides the ability to write *unsafe code*.

In unsafe code, it is possible to declare and operate on pointers, to perform conversions between pointers and integral types, to take the address of variables, and so forth. In a sense, writing unsafe code is much like writing C code within a C# program.

Unsafe code is in fact a “safe” feature from the perspective of both developers and users. Unsafe code shall be clearly marked with the modifier `unsafe`, so developers can’t possibly use unsafe features accidentally, and the execution engine works to ensure that unsafe code cannot be executed in an untrusted environment.

end note

22.2 Unsafe contexts

The unsafe features of C# are available only in unsafe contexts. An unsafe context is introduced by including an `unsafe` modifier in the declaration of a type, member, or local function, or by employing an *unsafe_statement*:

- A declaration of a class, struct, interface, or delegate may include an `unsafe` modifier, in which case, the entire textual extent of that type declaration (including the body of the class, struct, or interface) is considered an unsafe context.

Note: If the `type_declaration` is partial, only that part is an unsafe context. end note

- A declaration of a field, method, property, event, indexer, operator, instance constructor, finalizer, static constructor, or local function may include an `unsafe` modifier, in which case, the entire textual extent of that member declaration is considered an unsafe context.
- An *unsafe_statement* enables the use of an unsafe context within a *block*. The entire textual extent of the associated *block* is considered an unsafe context. A local function declared within an unsafe context is itself unsafe.

The associated grammar extensions are shown below and in subsequent subclauses.

ANTLR

```
unsafe_modifier
    : 'unsafe'
    ;

unsafe_statement
    : 'unsafe' block
    ;
```

Example: In the following code

C#

```
public unsafe struct Node
{
    public int Value;
    public Node* Left;
    public Node* Right;
}
```

the `unsafe` modifier specified in the struct declaration causes the entire textual extent of the struct declaration to become an unsafe context. Thus, it is possible to

declare the `Left` and `Right` fields to be of a pointer type. The example above could also be written

```
C#  
  
public struct Node  
{  
    public int Value;  
    public unsafe Node* Left;  
    public unsafe Node* Right;  
}
```

Here, the `unsafe` modifiers in the field declarations cause those declarations to be considered unsafe contexts.

end example

Other than establishing an unsafe context, thus permitting the use of pointer types, the `unsafe` modifier has no effect on a type or a member.

Example: In the following code

```
C#  
  
public class A  
{  
    public unsafe virtual void F()  
    {  
        char* p;  
        ...  
    }  
}  
  
public class B : A  
{  
    public override void F()  
    {  
        base.F();  
        ...  
    }  
}
```

the `unsafe` modifier on the `F` method in `A` simply causes the textual extent of `F` to become an unsafe context in which the unsafe features of the language can be used. In the override of `F` in `B`, there is no need to re-specify the `unsafe` modifier—unless, of course, the `F` method in `B` itself needs access to unsafe features.

The situation is slightly different when a pointer type is part of the method's signature

```
C#  
  
public unsafe class A  
{  
    public virtual void F(char* p) {...}  
}  
  
public class B: A  
{  
    public unsafe override void F(char* p) {...}  
}
```

Here, because `F`'s signature includes a pointer type, it can only be written in an unsafe context. However, the unsafe context can be introduced by either making the entire class unsafe, as is the case in `A`, or by including an `unsafe` modifier in the method declaration, as is the case in `B`.

end example

When the `unsafe` modifier is used on a partial type declaration (§14.2.7), only that particular part is considered an unsafe context.

22.3 Pointer types

In an unsafe context, a *type* (§8.1) can be a *pointer_type* as well as a *value_type*, a *reference_type*, or a *type_parameter*. In an unsafe context a *pointer_type* may also be the element type of an array (§16). A *pointer_type* may also be used in a *typeof* expression (§11.7.16) outside of an unsafe context (as such usage is not unsafe).

A *pointer_type* is written as an *unmanaged_type* (§8.8) or the keyword `void`, followed by a `*` token:

```
ANTLR  
  
pointer_type  
    : value_type ('*')+  
    | 'void' ('*')+  
    ;
```

The type specified before the `*` in a pointer type is called the *referent type* of the pointer type. It represents the type of the variable to which a value of the pointer type

points.

A *pointer_type* may only be used in an *array_type* in an unsafe context (§22.2). A *non_array_type* is any type that is not itself an *array_type*.

Unlike references (values of reference types), pointers are not tracked by the garbage collector—the garbage collector has no knowledge of pointers and the data to which they point. For this reason a pointer is not permitted to point to a reference or to a struct that contains references, and the referent type of a pointer shall be an *unmanaged_type*.

The intuitive rule for mixing of pointers and references is that referents of references (objects) are permitted to contain pointers, but referents of pointers are not permitted to contain references.

Example: Some examples of pointer types are given in the table below:

Example	Description
<code>byte*</code>	Pointer to <code>byte</code>
<code>char*</code>	Pointer to <code>char</code>
<code>int**</code>	Pointer to pointer to <code>int</code>
<code>int*[]</code>	Single-dimensional array of pointers to <code>int</code>
<code>void*</code>	Pointer to unknown type

end example

For a given implementation, all pointer types shall have the same size and representation.

Note: Unlike C and C++, when multiple pointers are declared in the same declaration, in C# the `*` is written along with the underlying type only, not as a prefix punctuator on each pointer name. For example:

```
C#
```

```
int* pi, pj; // NOT as int *pi, *pj;
```

end note

The value of a pointer having type `T*` represents the address of a variable of type `T`. The pointer indirection operator `*` (§22.6.2) can be used to access this variable.

Example: Given a variable `P` of type `int*`, the expression `*P` denotes the `int` variable found at the address contained in `P`. *end example*

Like an object reference, a pointer may be `null`. Applying the indirection operator to a `null`-valued pointer results in implementation-defined behavior (§22.6.2). A pointer with value `null` is represented by all-bits-zero.

The `void*` type represents a pointer to an unknown type. Because the referent type is unknown, the indirection operator cannot be applied to a pointer of type `void*`, nor can any arithmetic be performed on such a pointer. However, a pointer of type `void*` can be cast to any other pointer type (and vice versa) and compared to values of other pointer types (§22.6.8).

Pointer types are a separate category of types. Unlike reference types and value types, pointer types do not inherit from `object` and no conversions exist between pointer types and `object`. In particular, boxing and unboxing (§8.3.12) are not supported for pointers. However, conversions are permitted between different pointer types and between pointer types and the integral types. This is described in §22.5.

A *pointer_type* cannot be used as a type argument (§8.4), and type inference (§11.6.3) fails on generic method calls that would have inferred a type argument to be a pointer type.

A *pointer_type* cannot be used as a type of a subexpression of a dynamically bound operation (§11.3.3).

A *pointer_type* may be used as the type of a volatile field (§14.5.4).

Note: Although pointers can be passed as `ref` or `out` parameters, doing so can cause undefined behavior, since the pointer might well be set to point to a local variable that no longer exists when the called method returns, or the fixed object to which it used to point, is no longer fixed. For example:

```
C#  
  
class Test  
{  
    static int value = 20;  
  
    unsafe static void F(out int* pi1, ref int* pi2)  
    {
```

```

    int i = 10;
    pi1 = &i;
    fixed (int* pj = &value)
    {
        // ...
        pi2 = pj;
    }
}

static void Main()
{
    int i = 10;
    unsafe
    {
        int* px1;
        int* px2 = &i;
        F(out px1, ref px2);
        // Undefined behavior
        Console.WriteLine($"*px1 = {*px1}, *px2 = {*px2}");
    }
}
}

```

end note

A method can return a value of some type, and that type can be a pointer.

Example: When given a pointer to a contiguous sequence of `ints`, that sequence's element count, and some other `int` value, the following method returns the address of that value in that sequence, if a match occurs; otherwise it returns `null`:

```

C#

unsafe static int* Find(int* pi, int size, int value)
{
    for (int i = 0; i < size; ++i)
    {
        if (*pi == value)
        {
            return pi;
        }
        ++pi;
    }
    return null;
}

```

end example

In an unsafe context, several constructs are available for operating on pointers:

- The unary `*` operator may be used to perform pointer indirection (§22.6.2).
- The `->` operator may be used to access a member of a struct through a pointer (§22.6.3).
- The `[]` operator may be used to index a pointer (§22.6.4).
- The unary `&` operator may be used to obtain the address of a variable (§22.6.5).
- The `++` and `--` operators may be used to increment and decrement pointers (§22.6.6).
- The binary `+` and `-` operators may be used to perform pointer arithmetic (§22.6.7).
- The `==`, `!=`, `<`, `>`, `<=`, and `>=` operators may be used to compare pointers (§22.6.8).
- The `stackalloc` operator may be used to allocate memory from the call stack (§22.9).
- The `fixed` statement may be used to temporarily fix a variable so its address can be obtained (§22.7).

22.4 Fixed and moveable variables

The address-of operator (§22.6.5) and the `fixed` statement (§22.7) divide variables into two categories: *Fixed variables* and *moveable variables*.

Fixed variables reside in storage locations that are unaffected by operation of the garbage collector. (Examples of fixed variables include local variables, value parameters, and variables created by dereferencing pointers.) On the other hand, moveable variables reside in storage locations that are subject to relocation or disposal by the garbage collector. (Examples of moveable variables include fields in objects and elements of arrays.)

The `&` operator (§22.6.5) permits the address of a fixed variable to be obtained without restrictions. However, because a moveable variable is subject to relocation or disposal by the garbage collector, the address of a moveable variable can only be obtained using a `fixed` statement (§22.7), and that address remains valid only for the duration of that `fixed` statement.

In precise terms, a fixed variable is one of the following:

- A variable resulting from a *simple_name* (§11.7.4) that refers to a local variable, value parameter, or parameter array, unless the variable is captured by an anonymous function (§11.17.6.2).
- A variable resulting from a *member_access* (§11.7.6) of the form `v.I`, where `v` is a fixed variable of a *struct_type*.

- A variable resulting from a *pointer_indirection_expression* (§22.6.2) of the form `*P`, a *pointer_member_access* (§22.6.3) of the form `P->I`, or a *pointer_element_access* (§22.6.4) of the form `P[E]`.

All other variables are classified as moveable variables.

A static field is classified as a moveable variable. Also, a `ref` or `out` parameter is classified as a moveable variable, even if the argument given for the parameter is a fixed variable. Finally, a variable produced by dereferencing a pointer is always classified as a fixed variable.

22.5 Pointer conversions

22.5.1 General

In an unsafe context, the set of available implicit conversions (§10.2) is extended to include the following implicit pointer conversions:

- From any *pointer_type* to the type `void*`.
- From the `null` literal (§6.4.5.7) to any *pointer_type*.

Additionally, in an unsafe context, the set of available explicit conversions (§10.3) is extended to include the following explicit pointer conversions:

- From any *pointer_type* to any other *pointer_type*.
- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `ulong` to any *pointer_type*.
- From any *pointer_type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `ulong`.

Finally, in an unsafe context, the set of standard implicit conversions (§10.4.2) includes the following pointer conversions:

- From any *pointer_type* to the type `void*`.
- From the `null` literal to any *pointer_type*.

Conversions between two pointer types never change the actual pointer value. In other words, a conversion from one pointer type to another has no effect on the underlying address given by the pointer.

When one pointer type is converted to another, if the resulting pointer is not correctly aligned for the pointed-to type, the behavior is undefined if the result is dereferenced. In general, the concept “correctly aligned” is transitive: if a pointer to type `A` is correctly

aligned for a pointer to type `B`, which, in turn, is correctly aligned for a pointer to type `C`, then a pointer to type `A` is correctly aligned for a pointer to type `C`.

Example: Consider the following case in which a variable having one type is accessed via a pointer to a different type:

```
C#  
  
unsafe static void M()  
{  
    char c = 'A';  
    char* pc = &c;  
    void* pv = pc;  
    int* pi = (int*)pv;  
    int i = *pi; // undefined  
    *pi = 123456; // undefined  
}
```

end example

When a pointer type is converted to a pointer to `byte`, the result points to the lowest addressed `byte` of the variable. Successive increments of the result, up to the size of the variable, yield pointers to the remaining bytes of that variable.

Example: The following method displays each of the eight bytes in a `double` as a hexadecimal value:

```
C#  
  
class Test  
{  
    static void Main()  
    {  
        double d = 123.456e23;  
        unsafe  
        {  
            byte* pb = (byte*)&d;  
            for (int i = 0; i < sizeof(double); ++i)  
            {  
                Console.Write($" {*pb++:X2}");  
            }  
            Console.WriteLine();  
        }  
    }  
}
```

Of course, the output produced depends on endianness. One possibility is " BA FF 51 A2 90 6C 24 45".

end example

Mappings between pointers and integers are implementation-defined.

Note: However, on 32- and 64-bit CPU architectures with a linear address space, conversions of pointers to or from integral types typically behave exactly like conversions of `uint` or `ulong` values, respectively, to or from those integral types.

end note

22.5.2 Pointer arrays

Arrays of pointers can be constructed using *array_creation_expression* (§11.7.15.5) in an unsafe context. Only some of the conversions that apply to other array types are allowed on pointer arrays:

- The implicit reference conversion (§10.2.6) from any *array_type* to `System.Array` and the interfaces it implements also applies to pointer arrays. However, any attempt to access the array elements through `System.Array` or the interfaces it implements may result in an exception at run-time, as pointer types are not convertible to `object`.
- The implicit and explicit reference conversions (§10.2.6, §10.3.4) from a single-dimensional array type `S[]` to `System.Collections.Generic.IList<T>` and its generic base interfaces never apply to pointer arrays.
- The explicit reference conversion (§10.3.4) from `System.Array` and the interfaces it implements to any *array_type* applies to pointer arrays.
- The explicit reference conversions (§10.3.4) from `System.Collections.Generic.IList<S>` and its base interfaces to a single-dimensional array type `T[]` never applies to pointer arrays, since pointer types cannot be used as type arguments, and there are no conversions from pointer types to non-pointer types.

These restrictions mean that the expansion for the `foreach` statement over arrays described in §9.4.4.17 cannot be applied to pointer arrays. Instead, a `foreach` statement of the form

```
foreach (V v in x) embedded_statement
```

where the type of `x` is an array type of the form `T[, , ...,]`, `n` is the number of dimensions minus 1 and `T` or `V` is a pointer type, is expanded using nested for-loops as follows:

```
C#  
  
{  
    T[, , ..., ] a = x;  
    for (int i0 = a.GetLowerBound(0); i0 <= a.GetUpperBound(0); i0++)  
    {  
        for (int i1 = a.GetLowerBound(1); i1 <= a.GetUpperBound(1); i1++)  
        {  
            ...  
            for (int in = a.GetLowerBound(n); in <= a.GetUpperBound(n);  
in++)  
            {  
                V v = (V)a[i0,i1,...,in];  
                *embedded_statement*  
            }  
        }  
    }  
}
```

The variables `a`, `i0`, `i1`, ... `in` are not visible to or accessible to `x` or the *embedded_statement* or any other source code of the program. The variable `v` is read-only in the embedded statement. If there is not an explicit conversion (§22.5) from `T` (the element type) to `V`, an error is produced and no further steps are taken. If `x` has the value `null`, a `System.NullReferenceException` is thrown at run-time.

Note: Although pointer types are not permitted as type arguments, pointer arrays may be used as type arguments. *end note*

22.6 Pointers in expressions

22.6.1 General

In an unsafe context, an expression may yield a result of a pointer type, but outside an unsafe context, it is a compile-time error for an expression to be of a pointer type. In precise terms, outside an unsafe context a compile-time error occurs if any *simple_name* (§11.7.4), *member_access* (§11.7.6), *invocation_expression* (§11.7.8), or *element_access* (§11.7.10) is of a pointer type.

In an unsafe context, the *primary_no_array_creation_expression* (§11.7) and *unary_expression* (§11.8) productions permit additional constructs, which are described

in the following subclauses.

Note: The precedence and associativity of the unsafe operators is implied by the grammar. *end note*

22.6.2 Pointer indirection

A *pointer_indirection_expression* consists of an asterisk (*) followed by a *unary_expression*.

ANTLR

```
pointer_indirection_expression
    : '*' unary_expression
    ;
```

The unary * operator denotes pointer indirection and is used to obtain the variable to which a pointer points. The result of evaluating *P, where P is an expression of a pointer type T*, is a variable of type T. It is a compile-time error to apply the unary * operator to an expression of type void* or to an expression that isn't of a pointer type.

The effect of applying the unary * operator to a null-valued pointer is implementation-defined. In particular, there is no guarantee that this operation throws a `System.NullReferenceException`.

If an invalid value has been assigned to the pointer, the behavior of the unary * operator is undefined.

Note: Among the invalid values for dereferencing a pointer by the unary * operator are an address inappropriately aligned for the type pointed to (see example in §22.5), and the address of a variable after the end of its lifetime.

For purposes of definite assignment analysis, a variable produced by evaluating an expression of the form *P is considered initially assigned (§9.4.2).

22.6.3 Pointer member access

A *pointer_member_access* consists of a *primary_expression*, followed by a "->" token, followed by an *identifier* and an optional *type_argument_list*.

ANTLR

```
pointer_member_access
: primary_expression '->' identifier type_argument_list?
;
```

In a pointer member access of the form `P->I`, `P` shall be an expression of a pointer type, and `I` shall denote an accessible member of the type to which `P` points.

A pointer member access of the form `P->I` is evaluated exactly as `(*P).I`. For a description of the pointer indirection operator (`*`), see [§22.6.2](#). For a description of the member access operator (`.`), see [§11.7.6](#).

Example: In the following code

```
C#
struct Point
{
    public int x;
    public int y;
    public override string ToString() => $"({x},{y})";
}

class Test
{
    static void Main()
    {
        Point point;
        unsafe
        {
            Point* p = &point;
            p->x = 10;
            p->y = 20;
            Console.WriteLine(p->ToString());
        }
    }
}
```

the `->` operator is used to access fields and invoke a method of a struct through a pointer. Because the operation `P->I` is precisely equivalent to `(*P).I`, the `Main` method could equally well have been written:

```
C#
class Test
{
    static void Main()
    {
        Point point;
```

```

unsafe
{
    Point* p = &point;
    (*p).x = 10;
    (*p).y = 20;
    Console.WriteLine((*p).ToString());
}
}
}

```

end example

22.6.4 Pointer element access

A *pointer_element_access* consists of a *primary_no_array_creation_expression* followed by an expression enclosed in “[” and “]”.

ANTLR

```

pointer_element_access
: primary_no_array_creation_expression '[' expression ']'
;

```

In a pointer element access of the form `P[E]`, `P` shall be an expression of a pointer type other than `void*`, and `E` shall be an expression that can be implicitly converted to `int`, `uint`, `long`, or `ulong`.

A pointer element access of the form `P[E]` is evaluated exactly as `*(P + E)`. For a description of the pointer indirection operator (`*`), see §22.6.2. For a description of the pointer addition operator (`+`), see §22.6.7.

Example: In the following code

```

C#

class Test
{
    static void Main()
    {
        unsafe
        {
            char* p = stackalloc char[256];
            for (int i = 0; i < 256; i++)
            {
                p[i] = (char)i;
            }
        }
    }
}

```

```
}  
}
```

a pointer element access is used to initialize the character buffer in a `for` loop. Because the operation `P[E]` is precisely equivalent to `*(P + E)`, the example could equally well have been written:

```
C#  
  
class Test  
{  
    static void Main()  
    {  
        unsafe  
        {  
            char* p = stackalloc char[256];  
            for (int i = 0; i < 256; i++)  
            {  
                *(p + i) = (char)i;  
            }  
        }  
    }  
}
```

end example

The pointer element access operator does not check for out-of-bounds errors and the behavior when accessing an out-of-bounds element is undefined.

Note: This is the same as C and C++. *end note*

22.6.5 The address-of operator

An *addressof_expression* consists of an ampersand (`&`) followed by a *unary_expression*.

```
ANTLR
```

```
addressof_expression  
    : '&' unary_expression  
    ;
```

Given an expression `E` which is of a type `T` and is classified as a fixed variable (§22.4), the construct `&E` computes the address of the variable given by `E`. The type of the result is `T*` and is classified as a value. A compile-time error occurs if `E` is not classified as a variable, if `E` is classified as a read-only local variable, or if `E` denotes a moveable

variable. In the last case, a fixed statement (§22.7) can be used to temporarily “fix” the variable before obtaining its address.

Note: As stated in §11.7.6, outside an instance constructor or static constructor for a struct or class that defines a `readonly` field, that field is considered a value, not a variable. As such, its address cannot be taken. Similarly, the address of a constant cannot be taken.

The `&` operator does not require its argument to be definitely assigned, but following an `&` operation, the variable to which the operator is applied is considered definitely assigned in the execution path in which the operation occurs. It is the responsibility of the programmer to ensure that correct initialization of the variable actually does take place in this situation.

Example: In the following code

```
C#  
  
class Test  
{  
    static void Main()  
    {  
        int i;  
        unsafe  
        {  
            int* p = &i;  
            *p = 123;  
        }  
        Console.WriteLine(i);  
    }  
}
```

`i` is considered definitely assigned following the `&i` operation used to initialize `p`. The assignment to `*p` in effect initializes `i`, but the inclusion of this initialization is the responsibility of the programmer, and no compile-time error would occur if the assignment was removed.

end example

Note: The rules of definite assignment for the `&` operator exist such that redundant initialization of local variables can be avoided. For example, many external APIs take a pointer to a structure which is filled in by the API. Calls to such APIs typically pass the address of a local struct variable, and without the rule, redundant initialization of the struct variable would be required. *end note*

Note: When a local variable, value parameter, or parameter array is captured by an anonymous function (§11.7.21), that local variable, parameter, or parameter array is no longer considered to be a fixed variable (§22.7), but is instead considered to be a moveable variable. Thus it is an error for any unsafe code to take the address of a local variable, value parameter, or parameter array that has been captured by an anonymous function. *end note*

22.6.6 Pointer increment and decrement

In an unsafe context, the `++` and `--` operators (§11.7.14 and §11.8.6) can be applied to pointer variables of all types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
C#  
  
T* operator ++(T* x);  
T* operator --(T* x);
```

The operators produce the same results as `x+1` and `x-1`, respectively (§22.6.7). In other words, for a pointer variable of type `T*`, the `++` operator adds `sizeof(T)` to the address contained in the variable, and the `--` operator subtracts `sizeof(T)` from the address contained in the variable.

If a pointer increment or decrement operation overflows the domain of the pointer type, the result is implementation-defined, but no exceptions are produced.

22.6.7 Pointer arithmetic

In an unsafe context, the `+` operator (§11.9.5) and `-` operator (§11.9.6) can be applied to values of all pointer types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
C#  
  
T* operator +(T* x, int y);  
T* operator +(T* x, uint y);  
T* operator +(T* x, long y);  
T* operator +(T* x, ulong y);  
T* operator +(int x, T* y);  
T* operator +(uint x, T* y);  
T* operator +(long x, T* y);  
T* operator +(ulong x, T* y);  
T* operator -(T* x, int y);  
T* operator -(T* x, uint y);
```

```
T* operator -(T* x, long y);
T* operator -(T* x, ulong y);
long operator -(T* x, T* y);
```

Given an expression `P` of a pointer type `T*` and an expression `N` of type `int`, `uint`, `long`, or `ulong`, the expressions `P + N` and `N + P` compute the pointer value of type `T*` that results from adding `N * sizeof(T)` to the address given by `P`. Likewise, the expression `P - N` computes the pointer value of type `T*` that results from subtracting `N * sizeof(T)` from the address given by `P`.

Given two expressions, `P` and `Q`, of a pointer type `T*`, the expression `P - Q` computes the difference between the addresses given by `P` and `Q` and then divides that difference by `sizeof(T)`. The type of the result is always `long`. In effect, `P - Q` is computed as `((long)(P) - (long)(Q)) / sizeof(T)`.

Example:

```
C#
class Test
{
    static void Main()
    {
        unsafe
        {
            int* values = stackalloc int[20];
            int* p = &values[1];
            int* q = &values[15];
            Console.WriteLine($"p - q = {p - q}");
            Console.WriteLine($"q - p = {q - p}");
        }
    }
}
```

which produces the output:

```
Console
p - q = -14
q - p = 14
```

end example

If a pointer arithmetic operation overflows the domain of the pointer type, the result is truncated in an implementation-defined fashion, but no exceptions are produced.

22.6.8 Pointer comparison

In an unsafe context, the `==`, `!=`, `<`, `>`, `<=`, and `>=` operators (§11.11) can be applied to values of all pointer types. The pointer comparison operators are:

```
C#  
  
bool operator ==(void* x, void* y);  
bool operator !=(void* x, void* y);  
bool operator <(void* x, void* y);  
bool operator >(void* x, void* y);  
bool operator <=(void* x, void* y);  
bool operator >=(void* x, void* y);
```

Because an implicit conversion exists from any pointer type to the `void*` type, operands of any pointer type can be compared using these operators. The comparison operators compare the addresses given by the two operands as if they were unsigned integers.

22.6.9 The sizeof operator

For certain predefined types (§11.7.17), the `sizeof` operator yields a constant `int` value. For all other types, the result of the `sizeof` operator is implementation-defined and is classified as a value, not a constant.

The order in which members are packed into a struct is unspecified.

For alignment purposes, there may be unnamed padding at the beginning of a struct, within a struct, and at the end of the struct. The contents of the bits used as padding are indeterminate.

When applied to an operand that has struct type, the result is the total number of bytes in a variable of that type, including any padding.

22.7 The fixed statement

In an unsafe context, the *embedded_statement* (§12.1) production permits an additional construct, the fixed statement, which is used to “fix” a moveable variable such that its address remains constant for the duration of the statement.

```
ANTLR  
  
fixed_statement  
    : 'fixed' '(' pointer_type fixed_pointer_declarators ')'  
    embedded_statement
```

```

;

fixed_pointer_declarators
: fixed_pointer_declarator (',' fixed_pointer_declarator)*
;

fixed_pointer_declarator
: identifier '=' fixed_pointer_initializer
;

fixed_pointer_initializer
: '&' variable_reference
| expression
;

```

Each *fixed_pointer_declarator* declares a local variable of the given *pointer_type* and initializes that local variable with the address computed by the corresponding *fixed_pointer_initializer*. A local variable declared in a fixed statement is accessible in any *fixed_pointer_initializers* occurring to the right of that variable's declaration, and in the *embedded_statement* of the fixed statement. A local variable declared by a fixed statement is considered read-only. A compile-time error occurs if the embedded statement attempts to modify this local variable (via assignment or the `++` and `--` operators) or pass it as a `ref` or `out` parameter.

It is an error to use a captured local variable (§11.17.6.2), value parameter, or parameter array in a *fixed_pointer_initializer*. A *fixed_pointer_initializer* can be one of the following:

- The token `"&"` followed by a *variable_reference* (§9.5) to a moveable variable (§22.4) of an unmanaged type `T`, provided the type `T*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the given variable, and the variable is guaranteed to remain at a fixed address for the duration of the fixed statement.
- An expression of an *array_type* with elements of an unmanaged type `T`, provided the type `T*` is implicitly convertible to the pointer type given in the fixed statement. In this case, the initializer computes the address of the first element in the array, and the entire array is guaranteed to remain at a fixed address for the duration of the `fixed` statement. If the array expression is `null` or if the array has zero elements, the initializer computes an address equal to zero.
- An expression of type `string`, provided the type `char*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the first character in the string, and the entire string is guaranteed to remain at a fixed address for the duration of the `fixed` statement. The behavior of the `fixed` statement is implementation-defined if the string expression is `null`.

- A *simple_name* or *member_access* that references a fixed-size buffer member of a moveable variable, provided the type of the fixed-size buffer member is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes a pointer to the first element of the fixed-size buffer (§22.8.3), and the fixed-size buffer is guaranteed to remain at a fixed address for the duration of the `fixed` statement.

For each address computed by a *fixed_pointer_initializer* the `fixed` statement ensures that the variable referenced by the address is not subject to relocation or disposal by the garbage collector for the duration of the `fixed` statement.

Example: If the address computed by a *fixed_pointer_initializer* references a field of an object or an element of an array instance, the `fixed` statement guarantees that the containing object instance is not relocated or disposed of during the lifetime of the statement. *end example*

It is the programmer's responsibility to ensure that pointers created by `fixed` statements do not survive beyond execution of those statements.

Example: When pointers created by `fixed` statements are passed to external APIs, it is the programmer's responsibility to ensure that the APIs retain no memory of these pointers. *end example*

Fixed objects can cause fragmentation of the heap (because they can't be moved). For that reason, objects should be fixed only when absolutely necessary and then only for the shortest amount of time possible.

Example: The example

```
C#  
  
class Test  
{  
    static int x;  
    int y;  
  
    unsafe static void F(int* p)  
    {  
        *p = 1;  
    }  
  
    static void Main()  
    {  
        Test t = new Test();  
        int[] a = new int[10];  
    }  
}
```

```

unsafe
{
    fixed (int* p = &x) F(p);
    fixed (int* p = &t.y) F(p);
    fixed (int* p = &a[0]) F(p);
    fixed (int* p = a) F(p);
}
}
}

```

demonstrates several uses of the `fixed` statement. The first statement fixes and obtains the address of a static field, the second statement fixes and obtains the address of an instance field, and the third statement fixes and obtains the address of an array element. In each case, it would have been an error to use the regular `&` operator since the variables are all classified as moveable variables.

The third and fourth `fixed` statements in the example above produce identical results. In general, for an array instance `a`, specifying `a[0]` in a `fixed` statement is the same as simply specifying `a`.

end example

In an unsafe context, array elements of single-dimensional arrays are stored in increasing index order, starting with index `0` and ending with index `Length - 1`. For multi-dimensional arrays, array elements are stored such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left.

Within a `fixed` statement that obtains a pointer `p` to an array instance `a`, the pointer values ranging from `p` to `p + a.Length - 1` represent addresses of the elements in the array. Likewise, the variables ranging from `p[0]` to `p[a.Length - 1]` represent the actual array elements. Given the way in which arrays are stored, we can treat an array of any dimension as though it were linear.

Example:

```

C#
class Test
{
    static void Main()
    {
        int[, ] a = new int[2,3,4];
        unsafe
        {
            fixed (int* p = a)

```

```

    {
        for (int i = 0; i < a.Length; ++i) // treat as linear
        {
            p[i] = i;
        }
    }
}
for (int i = 0; i < 2; ++i)
{
    for (int j = 0; j < 3; ++j)
    {
        for (int k = 0; k < 4; ++k)
        {
            Console.WriteLine($"[{i},{j},{k}] = {a[i,j,k],2} ");
        }
        Console.WriteLine();
    }
}
}
}

```

which produces the output:

Console

```

[0,0,0] = 0 [0,0,1] = 1 [0,0,2] = 2 [0,0,3] = 3
[0,1,0] = 4 [0,1,1] = 5 [0,1,2] = 6 [0,1,3] = 7
[0,2,0] = 8 [0,2,1] = 9 [0,2,2] = 10 [0,2,3] = 11
[1,0,0] = 12 [1,0,1] = 13 [1,0,2] = 14 [1,0,3] = 15
[1,1,0] = 16 [1,1,1] = 17 [1,1,2] = 18 [1,1,3] = 19
[1,2,0] = 20 [1,2,1] = 21 [1,2,2] = 22 [1,2,3] = 23

```

end example

Example: In the following code

C#

```

class Test
{
    unsafe static void Fill(int* p, int count, int value)
    {
        for (; count != 0; count--)
        {
            *p++ = value;
        }
    }

    static void Main()
    {
        int[] a = new int[100];
    }
}

```

```

        unsafe
        {
            fixed (int* p = a) Fill(p, 100, -1);
        }
    }
}

```

a `fixed` statement is used to fix an array so its address can be passed to a method that takes a pointer.

end example

A `char*` value produced by fixing a string instance always points to a null-terminated string. Within a fixed statement that obtains a pointer `p` to a string instance `s`, the pointer values ranging from `p` to `p + s.Length - 1` represent addresses of the characters in the string, and the pointer value `p + s.Length` always points to a null character (the character with value `'\0'`).

Example:

```

C#

class Test
{
    static string name = "xx";

    unsafe static void F(char* p)
    {
        for (int i = 0; p[i] != '\0'; ++i)
        {
            System.Console.WriteLine(p[i]);
        }
    }

    static void Main()
    {
        unsafe
        {
            fixed (char* p = name) F(p);
            fixed (char* p = "xx") F(p);
        }
    }
}

```

end example

Modifying objects of managed type through fixed pointers can result in undefined behavior.

Note: For example, because strings are immutable, it is the programmer's responsibility to ensure that the characters referenced by a pointer to a fixed string are not modified. *end note*

Note: The automatic null-termination of strings is particularly convenient when calling external APIs that expect "C-style" strings. Note, however, that a string instance is permitted to contain null characters. If such null characters are present, the string will appear truncated when treated as a null-terminated `char*`. *end note*

22.8 Fixed-size buffers

22.8.1 General

Fixed-size buffers are used to declare "C-style" in-line arrays as members of structs, and are primarily useful for interfacing with unmanaged APIs.

22.8.2 Fixed-size buffer declarations

A *fixed-size buffer* is a member that represents storage for a fixed-length buffer of variables of a given type. A fixed-size buffer declaration introduces one or more fixed-size buffers of a given element type.

Note: Like an array, a fixed-size buffer can be thought of as containing elements. As such, the term *element type* as defined for an array is also used with a fixed-size buffer. *end note*

Fixed-size buffers are only permitted in struct declarations and may only occur in unsafe contexts (§22.2).

ANTLR

```
fixed_size_buffer_declaration
: attributes? fixed_size_buffer_modifier* 'fixed' buffer_element_type
  fixed_size_buffer_declarators ';'
;

fixed_size_buffer_modifier
: 'new'
| 'public'
```

```

| 'internal'
| 'private'
| 'unsafe'
;

buffer_element_type
: type
;

fixed_size_buffer_declarators
: fixed_size_buffer_declarator (',' fixed_size_buffer_declarator)*
;

fixed_size_buffer_declarator
: identifier '[' constant_expression ']'
;

```

A fixed-size buffer declaration may include a set of attributes (§21), a `new` modifier (§14.3.5), accessibility modifiers corresponding to any of the declared accessibilities permitted for struct members (§15.4.3) and an `unsafe` modifier (§22.2). The attributes and modifiers apply to all of the members declared by the fixed-size buffer declaration. It is an error for the same modifier to appear multiple times in a fixed-size buffer declaration.

A fixed-size buffer declaration is not permitted to include the `static` modifier.

The buffer element type of a fixed-size buffer declaration specifies the element type of the buffer(s) introduced by the declaration. The buffer element type shall be one of the predefined types `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, or `bool`.

The buffer element type is followed by a list of fixed-size buffer declarators, each of which introduces a new member. A fixed-size buffer declarator consists of an identifier that names the member, followed by a constant expression enclosed in `[` and `]` tokens. The constant expression denotes the number of elements in the member introduced by that fixed-size buffer declarator. The type of the constant expression shall be implicitly convertible to type `int`, and the value shall be a non-zero positive integer.

The elements of a fixed-size buffer shall be laid out sequentially in memory.

A fixed-size buffer declaration that declares multiple fixed-size buffers is equivalent to multiple declarations of a single fixed-size buffer declaration with the same attributes, and element types.

Example:

C#

```
unsafe struct A
{
    public fixed int x[5], y[10], z[100];
}
```

is equivalent to

C#

```
unsafe struct A
{
    public fixed int x[5];
    public fixed int y[10];
    public fixed int z[100];
}
```

end example

22.8.3 Fixed-size buffers in expressions

Member lookup (§11.5) of a fixed-size buffer member proceeds exactly like member lookup of a field.

A fixed-size buffer can be referenced in an expression using a *simple_name* (§11.6.3) or a *member_access* (§11.6.5).

When a fixed-size buffer member is referenced as a simple name, the effect is the same as a member access of the form `this.I`, where `I` is the fixed-size buffer member.

In a member access of the form `E.I`, if `E` is of a struct type and a member lookup of `I` in that struct type identifies a fixed-size member, then `E.I` is evaluated and classified as follows:

- If the expression `E.I` does not occur in an unsafe context, a compile-time error occurs.
- If `E` is classified as a value, a compile-time error occurs.
- Otherwise, if `E` is a moveable variable (§22.4) and the expression `E.I` is not a *fixed_pointer_initializer* (§22.7), a compile-time error occurs.
- Otherwise, `E` references a fixed variable and the result of the expression is a pointer to the first element of the fixed-size buffer member `I` in `E`. The result is of type `S*`, where `S` is the element type of `I`, and is classified as a value.

The subsequent elements of the fixed-size buffer can be accessed using pointer operations from the first element. Unlike access to arrays, access to the elements of a fixed-size buffer is an unsafe operation and is not range checked.

Example: The following declares and uses a struct with a fixed-size buffer member.

```
C#

unsafe struct Font
{
    public int size;
    public fixed char name[32];
}

class Test
{
    unsafe static void PutString(string s, char* buffer, int bufSize)
    {
        int len = s.Length;
        if (len > bufSize)
        {
            len = bufSize;
        }
        for (int i = 0; i < len; i++)
        {
            buffer[i] = s[i];
        }
        for (int i = len; i < bufSize; i++)
        {
            buffer[i] = (char)0;
        }
    }

    unsafe static void Main()
    {
        Font f;
        f.size = 10;
        PutString("Times New Roman", f.name, 32);
    }
}
```

end example

22.8.4 Definite assignment checking

Fixed-size buffers are not subject to definite assignment-checking ([§9.4](#)), and fixed-size buffer members are ignored for purposes of definite-assignment checking of struct type variables.

When the outermost containing struct variable of a fixed-size buffer member is a static variable, an instance variable of a class instance, or an array element, the elements of the fixed-size buffer are automatically initialized to their default values (§9.3). In all other cases, the initial content of a fixed-size buffer is undefined.

22.9 Stack allocation

In an unsafe context, a local variable declaration (§12.6.2) may include a stack allocation initializer, which allocates memory from the call stack.

ANTLR

```
stackalloc_initializer  
    : 'stackalloc' unmanaged_type '[' expression ']'  
    ;
```

The *unmanaged_type* (§8.8) indicates the type of the items that will be stored in the newly allocated location, and the *expression* indicates the number of these items. Taken together, these specify the required allocation size. Since the size of a stack allocation cannot be negative, it is a compile-time error to specify the number of items as a *constant_expression* that evaluates to a negative value.

A stack allocation initializer of the form `stackalloc T[E]` requires `T` to be an unmanaged type (§22.3) and `E` to be an expression implicitly convertible to type `int`. The construct allocates `E * sizeof(T)` bytes from the call stack and returns a pointer, of type `T*`, to the newly allocated block. If `E` is a negative value, then the behavior is undefined. If `E` is zero, then no allocation is made, and the pointer returned is implementation-defined. If there is not enough memory available to allocate a block of the given size, a `System.StackOverflowException` is thrown.

The content of the newly allocated memory is undefined.

Stack allocation initializers are not permitted in `catch` or `finally` blocks (§12.11).

Note: There is no way to explicitly free memory allocated using `stackalloc`. *end note*

All stack-allocated memory blocks created during the execution of a function member are automatically discarded when that function member returns.

Note: This corresponds to the `alloca` function, an extension commonly found in C and C++ implementations. *end note*

Example: In the following code

```
C#

class Test
{
    static string IntToString(int value)
    {
        if (value == int.MinValue)
        {
            return "-2147483648";
        }
        int n = value >= 0 ? value : -value;
        unsafe
        {
            char* buffer = stackalloc char[16];
            char* p = buffer + 16;
            do
            {
                *--p = (char)(n % 10 + '0');
                n /= 10;
            } while (n != 0);
            if (value < 0)
            {
                *--p = '-';
            }
            return new string(p, 0, (int)(buffer + 16 - p));
        }
    }

    static void Main()
    {
        Console.WriteLine(IntToString(12345));
        Console.WriteLine(IntToString(-999));
    }
}
```

a `stackalloc` initializer is used in the `IntToString` method to allocate a buffer of 16 characters on the stack. The buffer is automatically discarded when the method returns.

end example

Except for the `stackalloc` operator, C# provides no predefined constructs for managing non-garbage collected memory. Such services are typically provided by supporting class libraries or imported directly from the underlying operating system.

End of conditionally normative text.

Annex A Grammar

Article • 2022-12-01 • 23 minutes to read

This clause is informative.

A.1 General

This annex contains the grammar productions found in the specification, including the optional ones for unsafe code. Productions appear here in the same order in which they appear in the specification.

Annex B Portability issues

Article • 2023-01-17 • 3 minutes to read

This clause is informative.

B.1 General

This annex collects some information about portability that appears in this specification.

B.2 Undefined behavior

The behavior is undefined in the following circumstances:

1. The behavior of the enclosing async function when an awaiter's implementation of the interface methods `INotifyCompletion.OnCompleted` and `ICriticalNotifyCompletion.UnsafeOnCompleted` does not cause the resumption delegate to be invoked at most once (§11.8.8.4).
2. Passing pointers as `ref` or `out` parameters (§22.3).
3. When dereferencing the result of converting one pointer type to another and the resulting pointer is not correctly aligned for the pointed-to type. (§22.5.1).
4. When the unary `*` operator is applied to a pointer containing an invalid value (§22.6.2).
5. When a pointer is subscripted to access an out-of-bounds element (§22.6.4).
6. Modifying objects of managed type through fixed pointers (§22.7).
7. The content of memory newly allocated by `stackalloc` (§22.9).
8. Attempting to allocate a negative number of items using `stackalloc` (§22.9).

B.3 Implementation-defined behavior

A conforming implementation is required to document its choice of behavior in each of the areas listed in this subclause. The following are implementation-defined:

1. The behavior when an identifier not in Normalization Form C is encountered (§6.4.3).
2. The interpretation of the *input_characters* in the *pp_pragma-text* of a `#pragma` directive (§6.5.9).
3. The values of any application parameters passed to `Main` by the host environment prior to application startup (§7.1).

4. The precise structure of the expression tree, as well as the exact process for creating it, when an anonymous function is converted to an expression-tree (§10.7.3).
5. Whether a `System.ArithmeticException` (or a subclass thereof) is thrown or the overflow goes unreported with the resulting value being that of the left operand, when in an `unchecked` context and the left operand of an integer division is the maximum negative `int` or `long` value and the right operand is `-1` (§11.9.3).
6. When a `System.ArithmeticException` (or a subclass thereof) is thrown when performing a decimal remainder operation (§11.9.4).
7. The impact of thread termination when a thread has no handler for an exception, and the thread is itself terminated (§12.10.6).
8. The impact of thread termination when no matching `catch` clause is found for an exception and the code that initially started that thread is reached. (§20.4).
9. The mappings between pointers and integers (§22.5.1).
10. The effect of applying the unary `*` operator to a `null` pointer (§22.6.2).
11. The behavior when pointer arithmetic overflows the domain of the pointer type (§22.6.6, §22.6.7).
12. The result of the `sizeof` operator for non-pre-defined value types (§22.6.9).
13. The behavior of the `fixed` statement if the array expression is `null` or if the array has zero elements (§22.7).
14. The behavior of the `fixed` statement if the string expression is `null` (§22.7).
15. The value returned when a stack allocation of size zero is made (§22.9).

B.4 Unspecified behavior

1. The time at which the finalizer (if any) for an object is run, once that object has become eligible for finalization (§7.9).
2. The value of the result when converting out-of-range values from `float` or `double` values to an integral type in an `unchecked` context (§10.3.2).
3. The exact target object and target method of the delegate produced from an *anonymous_method_expression* contains (§10.7.2).
4. The layout of arrays, except in an unsafe context (§11.7.15.5).
5. Whether there is any way to execute the *block* of an anonymous function other than through evaluation and invocation of the *lambda_expression* or *anonymous_method-expression* (§11.17.3).
6. The exact timing of static field initialization (§14.5.6.2).
7. The result of invoking `MoveNext` when an enumerator object is running (§14.14.5.2).
8. The result of accessing `Current` when an enumerator object is in the before, running, or after states (§14.14.5.3).

9. The result of invoking `Dispose` when an enumerator object is in the running state (§14.14.5.4).
10. The attributes of a type declared in multiple parts are determined by combining, in an unspecified order, the attributes of each of its parts (§21.3).
11. The order in which members are packed into a struct (§22.6.9).
12. An exception occurs during finalizer execution, and that execution is not caught (§20.4).
13. If more than one member matches, which member is the implementation of I.M. (§17.6.5)

B.5 Other Issues

1. The exact results of floating-point expression evaluation can vary from one implementation to another, because an implementation is permitted to evaluate such expressions using a greater range and/or precision than is required. (§8.3.7)
2. The CLI reserves certain signatures for compatibility with other programming languages. (§14.3.10)

End of informative text.

Annex C Standard library

Article • 2022-04-09 • 20 minutes to read

C.1 General

A conforming C# implementation shall provide a minimum set of types having specific semantics. These types and their members are listed here, in alphabetical order by namespace and type. For a formal definition of these types and their members, refer to ISO/IEC 23271:2012 *Common Language Infrastructure (CLI), Partition IV; Base Class Library (BCL), Extended Numerics Library, and Extended Array Library*, which are included by reference in this specification.

This text is informative.

The standard library is intended to be the minimum set of types and members required by a conforming C# implementation. As such, it contains only those members that are explicitly required by the C# language specification.

It is expected that a conforming C# implementation will supply a significantly more extensive library that enables useful programs to be written. For example, a conforming implementation might extend this library by

- Adding namespaces.
- Adding types.
- Adding members to non-interface types.
- Adding intervening base classes or interfaces.
- Having struct and class types implement additional interfaces.
- Adding attributes (other than the `ConditionalAttribute`) to existing types and members.

End of informative text.

C.2 Standard Library Types defined in ISO/IEC 23271

```
C#
```

```
namespace System
{
    public delegate void Action();
}
```

```

public class ArgumentException : SystemException
{
    public ArgumentException();
    public ArgumentException(string message);
    public ArgumentException(string message, Exception innerException);
}

public class ArithmeticException : Exception
{
    public ArithmeticException();
    public ArithmeticException(string message);
    public ArithmeticException(string message, Exception
innerException);
}

public abstract class Array : IList, ICollection, IEnumerable
{
    public int Length { get; }
    public int Rank { get; }
    public int GetLength(int dimension);
}

public class ArrayTypeMismatchException : Exception
{
    public ArrayTypeMismatchException();
    public ArrayTypeMismatchException(string message);
    public ArrayTypeMismatchException(string message,
        Exception innerException);
}

[AttributeUsageAttribute(AttributeTargets.All, Inherited = true,
    AllowMultiple = false)]
public abstract class Attribute
{
    protected Attribute();
}

public enum AttributeTargets
{
    Assembly = 0x1,
    Module = 0x2,
    Class = 0x4,
    Struct = 0x8,
    Enum = 0x10,
    Constructor = 0x20,
    Method = 0x40,
    Property = 0x80,
    Field = 0x100,
    Event = 0x200,
    Interface = 0x400,
    Parameter = 0x800,
    Delegate = 0x1000,
    ReturnValue = 0x2000,
    GenericParameter = 0x4000,
    All = 0x7FFF
}

```

```

}

[AttributeUsageAttribute(AttributeTargets.Class, Inherited = true)]
public sealed class AttributeUsageAttribute : Attribute
{
    public AttributeUsageAttribute(AttributeTargets validOn);
    public bool AllowMultiple { get; set; }
    public bool Inherited { get; set; }
    public AttributeTargets ValidOn { get; }
}

public struct Boolean { }
public struct Byte { }

C.3 Standard Library Types not defined in ISO/IEC 23271

The following types, including the members listed, must be defined in a conforming standard library. (These types might be defined in a future edition of ISO/IEC 23271.) It is expected that many of these types will have more members available than are listed.

A conforming implementation may provide `Task.GetAwaiter()` and `Task<T>.GetAwaiter()` as extension methods.

```

C#

namespace System
{
    public class FormattableString : IFormattable { }
}

namespace System.Linq.Expressions
{
    public sealed class Expression<TDelegate>
    {
        public TDelegate Compile();
    }
}

namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Parameter, Inherited = false)]
    public sealed class CallerFilePathAttribute : Attribute
    {

```

```

    public CallerFilePathAttribute() { }
}

[AttributeUsage(AttributeTargets.Parameter, Inherited = false)]

GetAwaiter();
    }
}

```

```
}  
}
```

C.4 Format Specifications

The meaning of the formats, as used in interpolated string expressions (§11.7.3), are defined in ISO/IEC 23271:2012. For convenience the following text is copied from the description of `System.IFormattable`.

This text is informative.

A *format* is a string that describes the appearance of an object when it is converted to a string. Either standard or custom formats can be used. A standard format takes the form *Axx*, where *A* is a single alphabetic character called the *format specifier*, and *xx* is an integer between zero and 99 inclusive, called the *precision specifier*. The format specifier controls the type of formatting applied to the value being represented as a string. The *precision specifier* controls the number of significant digits or decimal places in the string, if applicable.

Note: For the list of standard format specifiers, see the table below. Note that a given data type, such as `System.Int32`, might not support one or more of the standard format specifiers. *end note*

Note: When a format includes symbols that vary by culture, such as the currencysymbol included by the 'C' and 'c' formats, a formatting object supplies the actual characters used in the string representation. A method might include a parameter to pass a `System.IFormatProvider` object that supplies a formatting object, or the method might use the default formatting object, which contains the symbol definitions for the current culture. The current culture typically uses the same set of symbols used system-wide by default. In the Base Class Library, the formatting object for system-supplied numeric types is a `System.Globalization.NumberFormatInfo` instance. For `System.DateTime` instances, a `System.Globalization.DateTimeFormatInfo` is used. *end note*

The following table describes the standard format specifiers and associated formatting object members that are used with numeric data types in the Base Class Library.

Format Specifier	Description
c	Currency Format: Used for strings containing a monetary value. The

c `System.Globalization.NumberFormatInfo.CurrencySymbol`,
`System.Globalization.NumberFormatInfo.CurrencyGroupSizes`,
`System.Globalization.NumberFormatInfo.CurrencyGroupSeparator`, and
`System.Globalization.NumberFormatInfo.CurrencyDecimalSeparator` members of a
`System.Globalization.NumberFormatInfo` supply the currency symbol, size and
separator for digit groupings, and decimal separator, respectively.

`System.Globalization.NumberFormatInfo.CurrencyNegativePattern` and
`System.Globalization.NumberFormatInfo.CurrencyPositivePattern` determine the
symbols used to represent negative and positive values. For example, a negative value
can be prefixed with a minus sign, or enclosed in parentheses.

If the precision specifier is omitted,
`System.Globalization.NumberFormatInfo.CurrencyDecimalDigits` determines the
number of decimal places in the string. Results are rounded to the nearest
representable value when necessary.

D **Decimal Format:** (This format is valid only when specified with integral data types.)
Used for strings containing integer values. Negative numbers are prefixed with the
d negative number symbol specified by the
`System.Globalization.NumberFormatInfo.NegativeSign` property.

The precision specifier determines the minimum number of digits that appear in the
string. If the specified precision requires more digits than the value contains, the
string is left-padded with zeros. If the precision specifier specifies fewer digits than are
in the value, the precision specifier is ignored.

E **Scientific (Engineering) Format:** Used for strings in one of the following forms:

e `[-]m.dddddE+xxx`

`[-]m.dddddE-xxx`

`[-]m.dddddE+xxx`

`[-]m.dddddE-xxx`

The negative number symbol ('-') appears only if the value is negative, and is supplied
by the `System.Globalization.NumberFormatInfo.NegativeSign` property.

Exactly one non-zero decimal digit (*m*) precedes the decimal separator ('.'), which is
supplied by the `System.Globalization.NumberFormatInfo.NumberDecimalSeparator`
property.

The precision specifier determines the number of decimal places (*dddddd*) in the
string. If the precision specifier is omitted, six decimal places are included in the string.

The exponent (*+/-xxx*) consists of either a positive or negative number symbol
followed by a minimum of three digits (*xxx*). The exponent is left-padded with zeros, if
necessary. The case of the format specifier ('E' or 'e') determines the case used for the
exponent prefix (E or e) in the string. Results are rounded to the nearest representable

value when necessary. The positive number symbol is supplied by the `System.Globalization.NumberFormatInfo.PositiveSign` property.

F **Fixed-Point Format:** Used for strings in the following form:

f `[-]m.dd...d`

At least one non-zero decimal digit (*m*) precedes the decimal separator ('.'), which is supplied by the `System.Globalization.NumberFormatInfo.NumberDecimalSeparator` property.

A negative number symbol sign ('-') precedes *m* only if the value is negative. This symbol is supplied by the `System.Globalization.NumberFormatInfo.NegativeSign` property.

The precision specifier determines the number of decimal places (*dd...d*) in the string. If the precision specifier is omitted, `System.Globalization.NumberFormatInfo.NumberDecimalDigits` determines the number of decimal places in the string. Results are rounded to the nearest representable value when necessary.

G **General Format:** The string is formatted in either fixed-point format ('F' or 'f') or scientific format ('E' or 'e').

g

For integral types:

Values are formatted using fixed-point format if *exponent* < precision specifier, where *exponent* is the exponent of the value in scientific format. For all other values, scientific format is used.

If the precision specifier is omitted, a default precision equal to the field width required to display the maximum value for the data type is used, which results in the value being formatted in fixed-point format. The default precisions for integral types are as follows:

`System.Int16`, `System.UInt16` : 5

`System.Int32`, `System.UInt32` : 10

`System.Int64`, `System.UInt64` : 19

For Single, Decimal and Double types:

Values are formatted using fixed-point format if *exponent* ≥ -4 and *exponent* < precision specifier, where *exponent* is the exponent of the value in scientific format. For all other values, scientific format is used. Results are rounded to the nearest representable value when necessary.

If the precision specifier is omitted, the following default precisions are used:

`System.Single` : 7

`System.Double` : 15

For all types:

- The number of digits that appear in the result (not including the exponent) will not exceed the value of the precision specifier; values are rounded as necessary.
- The decimal point and any trailing zeros after the decimal point are removed whenever possible.
- The case of the format specifier ('G' or 'g') determines whether 'E' or 'e' prefixes the scientific format exponent.

N

Number Format: Used for strings in the following form:

n

`[-]d,ddd,ddd.dd...d`

The representation of negative values is determined by the `System.Globalization.NumberFormatInfo.NumberNegativePattern` property. If the pattern includes a negative number symbol ('-'), this symbol is supplied by the `System.Globalization.NumberFormatInfo.NegativeSign` property.

At least one non-zero decimal digit (*d*) precedes the decimal separator ('.'), which is supplied by the `System.Globalization.NumberFormatInfo.NumberDecimalSeparator` property. Digits between the decimal point and the most significant digit in the value are grouped using the group size specified by the `System.Globalization.NumberFormatInfo.NumberGroupSizes` property. The group separator (',') is inserted between each digit group, and is supplied by the `System.Globalization.NumberFormatInfo.NumberGroupSeparator` property.

The precision specifier determines the number of decimal places (*dd...d*). If the precision specifier is omitted, `System.Globalization.NumberFormatInfo.NumberDecimalDigits` determines the number of decimal places in the string. Results are rounded to the nearest representable value when necessary.

P

Percent Format: Used for strings containing a percentage. The

P

`System.Globalization.NumberFormatInfo.PercentSymbol`, `System.Globalization.NumberFormatInfo.PercentGroupSizes`, `System.Globalization.NumberFormatInfo.PercentGroupSeparator`, and `System.Globalization.NumberFormatInfo.PercentDecimalSeparator` members of a `System.Globalization.NumberFormatInfo` supply the percent symbol, size and separator for digit groupings, and decimal separator, respectively.

`System.Globalization.NumberFormatInfo.PercentNegativePattern` and `System.Globalization.NumberFormatInfo.PercentPositivePattern` determine the symbols used to represent negative and positive values. For example, a negative value can be prefixed with a minus sign, or enclosed in parentheses.

If no precision is specified, the number of decimal places in the result is determined by `System.Globalization.NumberFormatInfo.PercentDecimalDigits`. Results are rounded to the nearest representable value when necessary.

The result is scaled by 100 (.99 becomes 99%).

R
r **Round trip Format:** (This format is valid only when specified with `System.Double` or `System.Single`.) Used to ensure that the precision of the string representation of a floating-point value is such that parsing the string does not result in a loss of precision when compared to the original value. If the maximum precision of the data type (7 for `System.Single`, and 15 for `System.Double`) would result in a loss of precision, the precision is increased by two decimal places. If a precision specifier is supplied with this format specifier, it is ignored. This format is otherwise identical to the fixed-point format.

X
x **Hexadecimal Format:** (This format is valid only when specified with integral data types.) Used for string representations of numbers in Base 16. The precision determines the minimum number of digits in the string. If the precision specifies more digits than the number contains, the number is left-padded with zeros. The case of the format specifier ('X' or 'x') determines whether upper case or lower case letters are used in the hexadecimal representation.

If the numerical value is a `System.Single` or `System.Double` with a value of `NaN`, `PositiveInfinity`, or `NegativeInfinity`, the format specifier is ignored, and one of the following is returned: `System.Globalization.NumberFormatInfo.NaNSymbol`, `System.Globalization.NumberFormatInfo.PositiveInfinitySymbol`, or `System.Globalization.NumberFormatInfo.NegativeInfinitySymbol`.

A custom format is any string specified as a format that is not in the form of a standard format string (Axx) described above. The following table describes the characters that are used in constructing custom formats.

Format Specifier	Description
0 (zero)	Zero placeholder: If the value being formatted has a digit in the position where a '0' appears in the custom format, then that digit is copied to the output string; otherwise a zero is stored in that position in the output string. The position of the leftmost '0' before the decimal separator and the rightmost '0' after the decimal separator determine the range of digits that are always present in the output string. The number of Zero and/or Digit placeholders after the decimal separator determines the number of digits that appear after the decimal separator. Values are rounded as necessary.
#	Digit placeholder: If the value being formatted has a digit in the position where a '#' appears in the custom format, then that digit is copied to the output string; otherwise, nothing is stored in that position in the output string. Note that this specifier never stores the '0' character if it is not a significant digit, even if '0' is the only digit in the string. (It does display the '0' character in the output string if it is a significant digit.)

The number of Zero and/or Digit placeholders after the decimal separator determines the number of digits that appear after the decimal separator. Values are rounded as necessary.

. (period) **Decimal separator:** The left most '.' character in the format string determines the location of the decimal separator in the formatted value; any additional '.' characters are ignored. The `System.Globalization.NumberFormatInfo.NumberDecimalSeparator` property determines the symbol used as the decimal separator.

, (comma) **Group separator and number scaling:** The ',' character serves two purposes. First, if the custom format contains this character between two Zero or Digit placeholders (0 or #) and to the left of the decimal separator if one is present, then the output will have group separators inserted between each group of digits to the left of the decimal separator. The `System.Globalization.NumberFormatInfo.NumberGroupSeparator` and `System.Globalization.NumberFormatInfo.NumberGroupSizes` properties determine the symbol used as the group separator and the number of digits in each group, respectively.

If the format string contains one or more ',' characters immediately to the left of the decimal separator, then the number will be scaled. The scale factor is determined by the number of group separator characters immediately to the left of the decimal separator. If there are x characters, then the value is divided by 1000^x before it is formatted. For example, the format string '0,,' will divide a value by one million. Note that the presence of the ',' character to indicate scaling does not insert group separators in the output string. Thus, to scale a number by 1 million and insert group separators, use a custom format similar to '#,##0,,'.

% (percent) **Percentage placeholder:** The presence of a '%' character in a custom format causes a number to be multiplied by 100 before it is formatted. The percent symbol is inserted in the output string at the location where the '%' appears in the format string. The `System.Globalization.NumberFormatInfo.PercentSymbol` property determines the percent symbol.

E0
E+0
E-0
e0
e+0
e-0 **Engineering format:** If any of the strings 'E', 'E+', 'E-', 'e', 'e+', or 'e-' are present in a custom format and is followed immediately by at least one '0' character, then the value is formatted using scientific notation. The number of '0' characters following the exponent prefix (E or e) determines the minimum number of digits in the exponent. The 'E+' and 'e+' formats indicate that a positive or negative number symbol always precedes the exponent. The 'E', 'E-', 'e', or 'e-' formats indicate that a negative number symbol precedes negative exponents; no symbol is precedes positive exponents. The positive number symbol is supplied by the `System.Globalization.NumberFormatInfo.PositiveSign` property. The negative number symbol is supplied by the `System.Globalization.NumberFormatInfo.NegativeSign` property.

**** (backslash) **Escape character:** In some languages, such as C#, the backslash character causes the next character in the custom format to be interpreted as an escape sequence. It is used with C language formatting sequences, such as '\n' (newline). In some

languages, the escape character itself is required to be preceded by an escape character when used as a literal. Otherwise, the compiler interprets the character as an escape sequence. This escape character is not required to be supported in all programming languages.

'ABC'

Literal string: Characters enclosed in single or double quotes are copied to the output string literally, and do not affect formatting.

"ABC"

;

(semicolon)

Section separator: The ';' character is used to separate sections for positive, negative, and zero numbers in the format string. (This feature is described in detail below.)

Other

All other characters: All other characters are stored in the output string as literals in the position in which they appear.

Note that for fixed-point format strings (strings not containing an 'E0', 'E+0', 'E-0', 'e0', 'e+0', or 'e-0'), numbers are rounded to as many decimal places as there are Zero or Digit placeholders to the right of the decimal separator. If the custom format does not contain a decimal separator, the number is rounded to the nearest integer. If the number has more digits than there are Zero or Digit placeholders to the left of the decimal separator, the extra digits are copied to the output string immediately before the first Zero or Digit placeholder.

A custom format can contain up to three sections separated by section separator characters, to specify different formatting for positive, negative, and zero values. The sections are interpreted as follows:

- **One section:** The custom format applies to all values (positive, negative and zero). Negative values include a negative sign.
- **Two sections:** The first section applies to positive values and zeros, and the second section applies to negative values. If the value to be formatted is negative, but becomes zero after rounding according to the format in the second section, then the resulting zero is formatted according to the first section. Negative values do not include a negative sign to allow full control over representations of negative values. For example, a negative can be represented in parenthesis using a custom format similar to '#####.#####;(#####.#####)'.
- **Three sections:** The first section applies to positive values, the second section applies to negative values, and the third section applies to zeros. The second section can be empty (nothing appears between the semicolons), in which case the first section applies to all nonzero values, and negative values include a negative sign. If the number to be formatted is nonzero, but becomes zero after rounding

according to the format in the first or second section, then the resulting zero is formatted according to the third section.

The `System.Enum` and `System.DateTime` types also support using format specifiers to format string representations of values. The meaning of a specific format specifier varies according to the kind of data (numeric, date/time, enumeration) being formatted. See `System.Enum` and `System.Globalization.DateTimeFormatInfo` for a comprehensive list of the format specifiers supported by each type.

C.5 Library Type Abbreviations

The following library types are referenced in this specification. The full names of those types, including the global namespace qualifier are listed below. Throughout this specification, these types appear as either the fully qualified name; with the global namespace qualifier omitted; or as a simple unqualified type name, with the namespace omitted as well. For example, the type `ICollection<T>`, when used in this specification, always means the type `global::System.Collections.Generic.ICollection<T>`.

- `global::System.Action`
- `global::System.ArgumentException`
- `global::System.ArithmeticException`
- `global::System.Array`
- `global::System.ArrayTypeMismatchException`
- `global::System.Attribute`
- `global::System.AttributeTargets`
- `global::System.AttributeUsageAttribute`
- `global::System.Boolean`
- `global::System.Byte`
- `global::System.Char`
- `global::System.Collections.Generic.ICollection<T>`
- `global::System.Collections.Generic.IEnumerable<T>`
- `global::System.Collections.Generic.IEnumerator<T>`
- `global::System.Collections.Generic.IList<T>`
- `global::System.Collections.Generic.IReadOnlyCollection<out T>`
- `global::System.Collections.Generic.IReadOnlyList<out T>`
- `global::System.Collections.ICollection`
- `global::System.Collections.IEnumerable`
- `global::System.Collections.IList`
- `global::System.Collections.IEnumerator`

- `global::System.Decimal`
- `global::System.Delegate`
- `global::System.Diagnostics.ConditionalAttribute`
- `global::System.DivideByZeroException`
- `global::System.Double`
- `global::System.Enum`
- `global::System.Exception`
- `global::System.GC`
- `global::System.ICollection`
- `global::System.IDisposable`
- `global::System.IEnumerable`
- `global::System.IEnumerable<out T>`
- `global::System.IList`
- `global::System.IndexOutOfRangeException`
- `global::System.Int16`
- `global::System.Int32`
- `global::System.Int64`
- `global::System.IntPtr`
- `global::System.InvalidCastException`
- `global::System.InvalidOperationException`
- `global::System.Linq.Expressions.Expression<TDelegate>`
- `global::System.MemberInfo`
- `global::System.NotSupportedException`
- `global::System.Nullable<T>`
- `global::System.NullReferenceException`
- `global::System.Object`
- `global::System.ObsoleteAttribute`
- `global::System.OutOfMemoryException`
- `global::System.OverflowException`
- `global::System.Runtime.CompilerServices.CallerFileAttribute`
- `global::System.Runtime.CompilerServices.CallerLineNumberAttribute`
- `global::System.Runtime.CompilerServices.CallerMemberNameAttribute`
- `global::System.Runtime.CompilerServices.ICriticalNotifyCompletion`
- `global::System.Runtime.CompilerServices.IndexerNameAttribute`
- `global::System.Runtime.CompilerServices.INotifyCompletion`

Annex D Documentation comments

Article • 2023-01-14 • 24 minutes to read

This annex is informative.

D.1 General

C# provides a mechanism for programmers to document their code using a comment syntax that contains XML text. In source code files, comments having a certain form can be used to direct a tool to produce XML from those comments and the source code elements, which they precede. Comments using such syntax are called **documentation comments**. They must immediately precede a user-defined type (such as a class, delegate, or interface) or a member (such as a field, event, property, or method). The XML generation tool is called the **documentation generator**. (This generator could be, but need not be, the C# compiler itself.) The output produced by the documentation generator is called the **documentation file**. A documentation file is used as input to a **documentation viewer**, a tool intended to produce some sort of visual display of type information and its associated documentation.

A conforming C# compiler is not required to check the syntax of documentation comments; such comments are simply ordinary comments. A conforming compiler is permitted to do such checking, however.

This specification suggests a set of standard tags to be used in documentation comments, but use of these tags is not required, and other tags may be used if desired, as long as the rules of well-formed XML are followed. For C# implementations targeting the CLI, it also provides information about the documentation generator and the format of the documentation file. No information is provided about the documentation viewer.

D.2 Introduction

Comments having a certain form can be used to direct a tool to produce XML from those comments and the source code elements that they precede. Such comments are *Single-Line_Comments* (§6.3.3) that start with three slashes (`///`), or *Delimited_Comments* (§6.3.3) that start with a slash and two asterisks (`/**`). They must immediately precede a user-defined type or a member that they annotate. Attribute sections (§21.3) are considered part of declarations, so documentation comments must precede attributes applied to a type or member.

For expository purposes, the format of document comments is shown below as two grammar rules: *Single_Line_Doc_Comment* and *Delimited_Doc_Comment*. However, these rules are *not* part of the C# grammar, but rather, they represent particular formats of *Single_Line_Comment* and *Delimited_Comment* lexer rules, respectively.

Syntax:

```
ANTLR

Single_Line_Doc_Comment
    : '///' Input_Character*
    ;

Delimited_Doc_Comment
    : '/*' Delimited_Comment_Section* ASTERISK+ '/'
    ;
```

In a *Single_Line_Doc_Comment*, if there is a *Whitespace* character following the `///` characters on each of the *Single_Line_Doc_Comments* adjacent to the current *Single_Line_Doc_Comment*, then that *Whitespace* character is not included in the XML output.

In a *Delimited_Doc_Comment*, if the first non-*Whitespace* character on the second line is an *ASTERISK* and the same pattern of optional *Whitespace* characters and an *ASTERISK* character is repeated at the beginning of each of the lines within the *Delimited_Doc_Comment*, then the characters of the repeated pattern are not included in the XML output. The pattern can include *Whitespace* characters after, as well as before, the *ASTERISK* character.

Example:

```
C#

/// <summary>
/// Class <c>Point</c> models a point in a two-dimensional plane.
/// </summary>
public class Point
{
    /// <summary>
    /// Method <c>Draw</c> renders the point.
    /// </summary>
    void Draw() {...}
}
```

The text within documentation comments must be well formed according to the rules of XML (<http://www.w3.org/TR/REC-xml>). If the XML is ill formed, a warning is generated

and the documentation file will contain a comment saying that an error was encountered.

Although developers are free to create their own set of tags, a recommended set is defined in §D.3. Some of the recommended tags have special meanings:

- The `<param>` tag is used to describe parameters. If such a tag is used, the documentation generator must verify that the specified parameter exists and that all parameters are described in documentation comments. If such verification fails, the documentation generator issues a warning.
- The `ceref` attribute can be attached to any tag to provide a reference to a code element. The documentation generator must verify that this code element exists. If the verification fails, the documentation generator issues a warning. When looking for a name described in a `ceref` attribute, the documentation generator must respect namespace visibility according to using statements appearing within the source code. For code elements that are generic, the normal generic syntax (e.g., "`List<T>`") cannot be used because it produces invalid XML. Braces can be used instead of brackets (e.g.; "`List{ T }`"), or the XML escape syntax can be used (e.g., "`List<T>`").
- The `<summary>` tag is intended to be used by a documentation viewer to display additional information about a type or member.
- The `<include>` tag includes information from an external XML file.

Note carefully that the documentation file does not provide full information about the type and members (for example, it does not contain any type information). To get such information about a type or member, the documentation file must be used in conjunction with reflection on the type or member.

D.3 Recommended tags

D.3.1 General

The documentation generator must accept and process any tag that is valid according to the rules of XML. The following tags provide commonly used functionality in user documentation. (Of course, other tags are possible.)

Tag	Reference	Purpose
<code><c></code>	§D.3.2	Set text in a code-like font

Tag	Reference	Purpose
<code><code></code>	§D.3.3	Set one or more lines of source code or program output
<code><example></code>	§D.3.4	Indicate an example
<code><exception></code>	§D.3.5	Identifies the exceptions a method can throw
<code><include></code>	§D.3.6	Includes XML from an external file
<code><list></code>	§D.3.7	Create a list or table
<code><para></code>	§D.3.8	Permit structure to be added to text
<code><param></code>	§D.3.9	Describe a parameter for a method or constructor
<code><paramref></code>	§D.3.10	Identify that a word is a parameter name
<code><permission></code>	§D.3.11	Document the security accessibility of a member
<code><remarks></code>	§D.3.12	Describe additional information about a type
<code><returns></code>	§D.3.13	Describe the return value of a method
<code><see></code>	§D.3.14	Specify a link
<code><seealso></code>	§D.3.15	Generate a <i>See Also</i> entry
<code><summary></code>	§D.3.16	Describe a type or a member of a type
<code><typeparam></code>	§D.3.17	Describe a type parameter for a generic type or method
<code><typeparamref></code>	§D.3.18	Identify that a word is a type parameter name
<code><value></code>	§D.3.19	Describe a property

D.3.2 <c>

This tag provides a mechanism to indicate that a fragment of text within a description should be set in a special font such as that used for a block of code. For lines of actual code, use `<code>` ([§D.3.3](#)).

Syntax:

```
<c>text</c>
```

Example:

```
C#
```

```
/// <summary>
/// Class <c>Point</c> models a point in a two-dimensional plane.
/// </summary>
public class Point
{
}
```

D.3.3 <code>

This tag is used to set one or more lines of source code or program output in some special font. For small code fragments in narrative, use `<c>` (§D.3.2).

Syntax:

```
<code>source code or program output</code>
```

Example:

```
C#

public class Point
{
    /// <summary>
    /// This method changes the point's location by the given x- and y-
    /// offsets.
    /// <example>
    /// For example:
    /// <code>
    /// Point p = new Point(3,5);
    /// p.Translate(-1,3);
    /// </code>
    /// results in <c>p</c>'s having the value (2,8).
    /// </example>
    /// </summary>
    public void Translate(int dx, int dy)
    {
        ...
    }
}
```

D.3.4 <example>

This tag allows example code within a comment, to specify how a method or other library member might be used. Ordinarily, this would also involve use of the tag `<code>` (§D.3.3) as well.

Syntax:

`<example>description</example>`

Example:

See `<code>` ([§D.3.3](#)) for an example.

D.3.5 `<exception>`

This tag provides a way to document the exceptions a method can throw.

Syntax:

```
<exception cref="member">description</exception>
```

where

- `cref="member"` is the name of a member. The documentation generator checks that the given member exists and translates *member* to the canonical element name in the documentation file.
- *description* is a description of the circumstances in which the exception is thrown.

Example:

C#

```
class MasterFileFormatCorruptException : System.Exception { ... }
class MasterFileLockedOpenException : System.Exception { ... }

public class DataBaseOperations
{
    /// <exception cref="MasterFileFormatCorruptException">
    /// Thrown when the master file is corrupted.
    /// </exception>
    /// <exception cref="MasterFileLockedOpenException">
    /// Thrown when the master file is already open.
    /// </exception>
    public static void ReadRecord(int flag)
    {
        if (flag == 1)
        {
            throw new MasterFileFormatCorruptException();
        }
        else if (flag == 2)
        {
            throw new MasterFileLockedOpenException();
        }
        ...
    }
}
```

D.3.6 <include>

This tag allows including information from an XML document that is external to the source code file. The external file must be a well-formed XML document, and an XPath expression is applied to that document to specify what XML from that document to include. The `<include>` tag is then replaced with the selected XML from the external document.

Syntax:

```
<include file="filename" path="xpath" />
```

where

- `file="filename"` is the file name of an external XML file. The file name is interpreted relative to the file that contains the include tag.
- `path="xpath"` is an XPath expression that selects some of the XML in the external XML file.

Example:

If the source code contained a declaration like:

```
C#  
  
/// <include file="docs.xml" path='extradoc/class[@name="IntList"]/*' />  
public class IntList { ... }
```

and the external file "docs.xml" had the following contents:

```
XML  
  
<?xml version="1.0"?>  
<extradoc>  
  <class name="IntList">  
    <summary>  
      Contains a list of integers.  
    </summary>  
  </class>  
  <class name="StringList">  
    <summary>  
      Contains a list of strings.  
    </summary>  
  </class>  
</extradoc>
```

then the same documentation is output as if the source code contained:

C#

```
/// <summary>
/// Contains a list of integers.
/// </summary>
public class IntList { ... }
```

D.3.7 <list>

This tag is used to create a list or table of items. It can contain a `<listheader>` block to define the heading row of either a table or definition list. (When defining a table, only an entry for *term* in the heading need be supplied.)

Each item in the list is specified with an `<item>` block. When creating a definition list, both *term* and *description* must be specified. However, for a table, bulleted list, or numbered list, only *description* need be specified.

Syntax:

XML

```
<list type="bullet" | "number" | "table">
  <listheader>
    <term>term</term>
    <description>description</description>
  </listheader>
  <item>
    <term>term</term>
    <description>description</description>
  </item>
  ...
  <item>
    <term>term</term>
    <description>description</description>
  </item>
</list>
```

where

- *term* is the term to define, whose definition is in *description*.
- *description* is either an item in a bullet or numbered list, or the definition of a *term*.

Example:

C#

```

public class MyClass
{
    /// <summary>Here is an example of a bulleted list:
    /// <list type="bullet">
    /// <item>
    /// <description>Item 1.</description>
    /// </item>
    /// <item>
    /// <description>Item 2.</description>
    /// </item>
    /// </list>
    /// </summary>
    public static void Main()
    {
        ...
    }
}

```

D.3.8 <para>

This tag is for use inside other tags, such as `<summary>` (§D.3.16) or `<returns>` (§D.3.13), and permits structure to be added to text.

Syntax:

```
<para>content</para>
```

where

- *content* is the text of the paragraph.

Example:

```

C#

public class Point
{
    /// <summary>This is the entry point of the Point class testing program.
    /// <para>
    /// This program tests each method and operator, and
    /// is intended to be run after any non-trivial maintenance has
    /// been performed on the Point class.
    /// </para>
    /// </summary>
    public static void Main()
    {
        ...
    }
}

```

D.3.9 <param>

This tag is used to describe a parameter for a method, constructor, or indexer.

Syntax:

```
<param name="name">description</param>
```

where

- *name* is the name of the parameter.
- *description* is a description of the parameter.

Example:

C#

```
public class Point
{
    /// <summary>
    /// This method changes the point's location to
    /// the given coordinates.
    /// </summary>
    /// <param name="xPosition">the new x-coordinate.</param>
    /// <param name="yPosition">the new y-coordinate.</param>
    public void Move(int xPosition, int yPosition)
    {
        ...
    }
}
```

D.3.10 <paramref>

This tag is used to indicate that a word is a parameter. The documentation file can be processed to format this parameter in some distinct way.

Syntax:

```
<paramref name="name"/>
```

where

- *name* is the name of the parameter.

Example:

C#

```

public class Point
{
    /// <summary>This constructor initializes the new Point to
    /// (<paramref name="xPosition"/>,<paramref name="yPosition"/>).
    /// </summary>
    /// <param name="xPosition">the new Point's x-coordinate.</param>
    /// <param name="yPosition">the new Point's y-coordinate.</param>
    public Point(int xPosition, int yPosition)
    {
        ...
    }
}

```

D.3.11 <permission>

This tag allows the security accessibility of a member to be documented.

Syntax:

```
<permission cref="member">description</permission>
```

where

- *member* is the name of a member. The documentation generator checks that the given code element exists and translates *member* to the canonical element name in the documentation file.
- *description* is a description of the access to the member.

Example:

```

C#

public class MyClass
{
    /// <permission cref="System.Security.PermissionSet">
    /// Everyone can access this method.
    /// </permission>
    public static void Test()
    {
        ...
    }
}

```

D.3.12 <remarks>

This tag is used to specify extra information about a type. Use `<summary>` ([§D.3.16](#)) to describe the type itself and the members of a type.

Syntax:

```
<remarks>description</remarks>
```

where

- *description* is the text of the remark.

Example:

C#

```
/// <summary>
/// Class <c>Point</c> models a point in a two-dimensional plane.
/// </summary>
/// <remarks>
/// Uses polar coordinates
/// </remarks>
public class Point
{
    ...
}
```

D.3.13 <returns>

This tag is used to describe the return value of a method.

Syntax:

```
<returns>description</returns>
```

where

- *description* is a description of the return value.

Example:

C#

```
public class Point
{
    /// <summary>
    /// Report a point's location as a string.
    /// </summary>
    /// <returns>
    /// A string representing a point's location, in the form (x,y),
```

```

    /// without any leading, trailing, or embedded whitespace.
    /// </returns>
    public override string ToString() => $"({X},{Y})";
    public int X { get; set; }
    public int Y { get; set; }
}

```

D.3.14 <see>

This tag allows a link to be specified within text. Use `<seealso>` ([§D.3.15](#)) to indicate text that is to appear in a *See Also* subclause.

Syntax:

```
<see cref="member" href="url" langword="keyword" />
```

where

- *member* is the name of a member. The documentation generator checks that the given code element exists and changes *member* to the element name in the generated documentation file.
- *url* is a reference to an external source.
- *langword* is a word to be highlighted somehow.

Example:

```

C#

public class Point
{
    /// <summary>
    /// This method changes the point's location to
    /// the given coordinates. <see cref="Translate"/>
    /// </summary>
    public void Move(int xPosition, int yPosition)
    {
        ...
    }
    /// <summary>This method changes the point's location by
    /// the given x- and y-offsets. <see cref="Move"/>
    /// </summary>
    public void Translate(int dx, int dy)
    {
        ...
    }
}

```

D.3.15 <seealso>

This tag allows an entry to be generated for the *See Also* subclause. Use `<see>` (§D.3.14) to specify a link from within text.

Syntax:

```
<seealso cref="member" href="url" />
```

where

- *member* is the name of a member. The documentation generator checks that the given code element exists and changes *member* to the element name in the generated documentation file.
- *url* is a reference to an external source.

Example:

C#

```
public class Point
{
    /// <summary>
    /// This method determines whether two Points have the same location.
    /// </summary>
    /// <seealso cref="operator==" />
    /// <seealso cref="operator!=" />
    public override bool Equals(object o)
    {
        ...
    }
}
```

D.3.16 <summary>

This tag can be used to describe a type or a member of a type. Use `<remarks>` (§D.3.12) to describe the type itself.

Syntax:

```
<summary>description</summary>
```

where

- *description* is a summary of the type or member.

Example:

C#

```
public class Point
{
    /// <summary>
    /// This constructor initializes the new Point to
    /// (<paramref name="xPosition"/>,<paramref name="yPosition"/>).
    /// </summary>
    public Point(int xPosition, int yPosition)
    {
        ...
    }

    /// <summary>This constructor initializes the new Point to (0,0).
</summary>
    public Point() : this(0, 0)
    {
    }
}
```

D.3.17 <typeparam>

This tag is used to describe a type parameter for a generic type or method.

Syntax:

```
<typeparam name="name">description</typeparam>
```

where

- *name* is the name of the type parameter.
- *description* is a description of the type parameter.

Example:

C#

```
/// <summary>A generic list class.</summary>
/// <typeparam name="T">The type stored by the list.</typeparam>
public class MyList<T>
{
    ...
}
```

D.3.18 <typeparamref>

This tag is used to indicate that a word is a type parameter. The documentation file can be processed to format this type parameter in some distinct way.

Syntax:

```
<typeparamref name="name" />
```

where

- *name* is the name of the type parameter.

Example:

```
C#  
  
public class MyClass  
{  
    /// <summary>  
    /// This method fetches data and returns a list of  
    /// <typeparamref name="T"/>.  
    /// </summary>  
    /// <param name="string">query to execute</param>  
    public List<T> FetchData<T>(string query)  
    {  
        ...  
    }  
}
```

D.3.19 <value>

This tag allows a property to be described.

Syntax:

```
<value>property description </value>
```

where

- *property description* is a description for the property.

Example:

```
C#  
  
public class Point  
{  
    /// <value>Property <c>X</c> represents the point's x-coordinate.  
    </value>
```

```
public int X { get; set; }  
}
```

D.4 Processing the documentation file

D.4.1 General

The following information is intended for C# implementations targeting the CLI.

The documentation generator generates an ID string for each element in the source code that is tagged with a documentation comment. This ID string uniquely identifies a source element. A documentation viewer can use an ID string to identify the corresponding item to which the documentation applies.

The documentation file is not a hierarchical representation of the source code; rather, it is a flat list with a generated ID string for each element.

D.4.2 ID string format

The documentation generator observes the following rules when it generates the ID strings:

- No white space is placed in the string.
- The first part of the string identifies the kind of member being documented, via a single character followed by a colon. The following kinds of members are defined:

Character	Description
E	Event
F	Field
M	Method (including constructors, finalizers, and operators)
N	Namespace
P	Property (including indexers)
T	Type (such as class, delegate, enum, interface, and struct)
!	Error string; the rest of the string provides information about the error. For example, the documentation generator generates error information for links that cannot be resolved.

- The second part of the string is the fully qualified name of the element, starting at the root of the namespace. The name of the element, its enclosing type(s), and namespace are separated by periods. If the name of the item itself has periods, they are replaced by # (U+0023) characters. (It is assumed that no element has this character in its name.)
- For methods and properties with arguments, the argument list follows, enclosed in parentheses. For those without arguments, the parentheses are omitted. The arguments are separated by commas. The encoding of each argument is the same as a CLI signature, as follows:
 - Arguments are represented by their documentation name, which is based on their fully qualified name, modified as follows:
 - Arguments that represent generic types have an appended "T" character followed by the number of type parameters
 - Arguments having the `out` or `ref` modifier have an @ following their type name. Arguments passed by value or via `params` have no special notation.
 - Arguments that are arrays are represented as `[lowerbound : size , ... , lowerbound : size]` where the number of commas is the rank less one, and the lower bounds and size of each dimension, if known, are represented in decimal. If a lower bound or size is not specified, it is omitted. If the lower bound and size for a particular dimension are omitted, the ":" is omitted as well. Jagged arrays are represented by one "[]" per level.
 - Arguments that have pointer types other than `void` are represented using a * following the type name. A `void` pointer is represented using a type name of `System.Void`.
 - Arguments that refer to generic type parameters defined on types are encoded using the "T" character followed by the zero-based index of the type parameter.
 - Arguments that use generic type parameters defined in methods use a double-backtick "`" instead of the "T" used for types.
 - Arguments that refer to constructed generic types are encoded using the generic type, followed by "{", followed by a comma-separated list of type arguments, followed by "}".

D.4.3 ID string examples

The following examples each show a fragment of C# code, along with the ID string produced from each source element capable of having a documentation comment:

Types are represented using their fully qualified name, augmented with generic information:

C#

```
enum Color { Red, Blue, Green }

namespace Acme
{
    interface IProcess { ... }

    struct ValueType { ... }

    class Widget : IProcess
    {
        public class NestedClass { ... }
        public interface IMenuItem { ... }
        public delegate void Del(int i);
        public enum Direction { North, South, East, West }
    }

    class MyList<T>
    {
        class Helper<U,V> { ... }
    }
}
```

IDs:

Console

```
"T:Color"
"T:Acme.IProcess"
"T:Acme.ValueType"
"T:Acme.Widget"
"T:Acme.Widget.NestedClass"
"T:Acme.Widget.IMenuItem"
"T:Acme.Widget.Del"
"T:Acme.Widget.Direction"
"T:Acme.MyList`1"
"T:Acme.MyList`1.Helper`2"
```

Fields are represented by their fully qualified name.

C#

```
namespace Acme
{
    struct ValueType
    {
        private int total;
    }
}
```

```

    }

    class Widget : IProcess
    {
        public class NestedClass
        {
            private int value;
        }

        private string message;
        private static Color defaultColor;
        private const double PI = 3.14159;
        protected readonly double monthlyAverage;
        private long[] array1;
        private Widget[,] array2;
        private unsafe int *pCount;
        private unsafe float **ppValues;
    }
}

```

IDs:

Console

```

"F:Acme.ValueType.total"
"F:Acme.Widget.NestedClass.value"
"F:Acme.Widget.message"
"F:Acme.Widget.defaultColor"
"F:Acme.Widget.PI"
"F:Acme.Widget.monthlyAverage"
"F:Acme.Widget.array1"
"F:Acme.Widget.array2"
"F:Acme.Widget.pCount"
"F:Acme.Widget.ppValues"

```

Constructors

C#

```

namespace Acme
{

"P:Acme.Widget.Item(System.Int32)"

```

```
"P:Acme.Widget.Item(System.String,System.Int32)"
```

Events

C#

```
namespace Acme
{
    class Widget : IProcess
    {
        public event Del AnEvent;
    }
}
```

IDs:

Console

```
"E:Acme.Widget.AnEvent"
```

Unary operators

C#

```
namespace Acme
{
    class Widget : IProcess
    {
        public static Widget operator+(Widget x) { ... }
    }
}
```

IDs:

Console

```
"M:Acme.Widget.op_UnaryPlus(Acme.Widget)"
```

The complete set of unary operator function names used is as follows: `op_UnaryPlus`, `op_UnaryNegation`, `op_LogicalNot`, `op_OnesComplement`, `op_Increment`, `op_Decrement`, `op_True`, and `op_False`.

Binary operators

C#

```

namespace Acme
{
    class Widget : IProcess
    {
        public static Widget operator+(Widget x1, Widget x2) { ... }
    }
}

```

IDs:

Console

```
"M:Acme.Widget.op_Addition(Acme.Widget,Acme.Widget)"
```

The complete set of binary operator function names used is as follows: `op_Addition`, `op_Subtraction`, `op_Multiply`, `op_Division`, `op_Modulus`, `op_BitwiseAnd`, `op_BitwiseOr`, `op_ExclusiveOr`, `op_LeftShift`, `op_RightShift`, `op_Equality`, `op_Inequality`, `op_LessThan`, `op_LessThanOrEqual`, `op_GreaterThan`, and `op_GreaterThanOrEqual`.

Conversion operators have a trailing `~` followed by the return type.

C#

```

namespace Acme
{
    class Widget : IProcess
    {
        public static explicit operator int(Widget x) { ... }
        public static implicit operator long(Widget x) { ... }
    }
}

```

IDs:

Console

```
"M:Acme.Widget.op_Explicit(Acme.Widget)~System.Int32"
"M:Acme.Widget.op_Implicit(Acme.Widget)~System.Int64"
```

D.5 An example

D.5.1 C# source code

The following example shows the source code of a Point class:

C#

```
namespace Graphics
{
    /// <summary>
    /// Class <c>Point</c> models a point in a two-dimensional plane.
    /// </summary>
    public class Point
    {
        /// <value>
        /// Property <c>X</c> represents the point's x-coordinate.
        /// </value>
        public int X { get; set; }

        /// <value>
        /// Property <c>Y</c> represents the point's y-coordinate.
        /// </value>
        public int Y { get; set; }

        /// <summary>
        /// This constructor initializes the new Point to (0,0).
        /// </summary>
        public Point() : this(0, 0) {}

        /// <summary>
        /// This constructor initializes the new Point to
        /// (<paramref name="xPosition"/>,<paramref name="yPosition"/>).
        /// </summary>
        /// <param><c>xPosition</c> is the new Point's x-coordinate.</param>
        /// <param><c>yPosition</c> is the new Point's y-coordinate.</param>
        public Point(int xPosition, int yPosition)
        {
            X = xPosition;
            Y = yPosition;
        }

        /// <summary>
        /// This method changes the point's location to
        /// the given coordinates. <see cref="Translate"/>
        /// </summary>
        /// <param><c>xPosition</c> is the new x-coordinate.</param>
        /// <param><c>yPosition</c> is the new y-coordinate.</param>
        public void Move(int xPosition, int yPosition)
        {
            X = xPosition;
            Y = yPosition;
        }

        /// <summary>
        /// This method changes the point's location by
        /// the given x- and y-offsets.
        /// <example>For example:
        /// <code>
        /// Point p = new Point(3, 5);
```

```

    /// p.Translate(-1, 3);
    /// </code>
    /// results in <c>p</c>'s having the value (2, 8).
    /// <see cref="Move"/>
    /// </example>
    /// </summary>
    /// <param><c>dx</c> is the relative x-offset.</param>
    /// <param><c>dy</c> is the relative y-offset.</param>
    public void Translate(int dx, int dy)
    {
        X += dx;
        Y += dy;
    }

    /// <summary>
    /// This method determines whether two Points have the same
location.
    /// </summary>
    /// <param>

Pattern Matching for C# 7

Article • 2021-09-21 • 15 minutes to read

Pattern matching extensions for C# enable many of the benefits of algebraic data types and pattern matching from functional languages, but in a way that smoothly integrates with the feel of the underlying language. The basic features are: [record types](#), which are types whose semantic meaning is described by the shape of the data; and pattern matching, which is a new expression form that enables extremely concise multilevel decomposition of these data types. Elements of this approach are inspired by related features in the programming languages [F#](#) and [Scala](#).

Is expression

The `is` operator is extended to test an expression against a *pattern*.

```
antlr
relational_expression
    : relational_expression 'is' pattern
    ;
```

This form of *relational_expression* is in addition to the existing forms in the C# specification. It is a compile-time error if the *relational_expression* to the left of the `is` token does not designate a value or does not have a type.

Every *identifier* of the pattern introduces a new local variable that is *definitely assigned* after the `is` operator is `true` (i.e. *definitely assigned when true*).

Note: There is technically an ambiguity between *type* in an `is-expression` and *constant_pattern*, either of which might be a valid parse of a qualified identifier. We try to bind it as a type for compatibility with previous versions of the language; only if that fails do we resolve it as we do in other contexts, to the first thing found (which must be either a constant or a type). This ambiguity is only present on the right-hand-side of an `is` expression.

Patterns

Patterns are used in the `is` operator and in a *switch_statement* to express the shape of data against which incoming data is to be compared. Patterns may be recursive so that parts of the data may be matched against sub-patterns.

```
antlr
```

```
pattern
  : declaration_pattern
  | constant_pattern
  | var_pattern
  ;

declaration_pattern
  : type simple_designation
  ;

constant_pattern
  : shift_expression
  ;

var_pattern
  : 'var' simple_designation
  ;
```

Note: There is technically an ambiguity between *type* in an `is-expression` and *constant_pattern*, either of which might be a valid parse of a qualified identifier. We try to bind it as a type for compatibility with previous versions of the language; only if that fails do we resolve it as we do in other contexts, to the first thing found (which must be either a constant or a type). This ambiguity is only present on the right-hand-side of an `is` expression.

Declaration pattern

The *declaration_pattern* both tests that an expression is of a given type and casts it to that type if the test succeeds. If the *simple_designation* is an identifier, it introduces a local variable of the given type named by the given identifier. That local variable is *definitely assigned* when the result of the pattern-matching operation is true.

```
antlr
```

```
declaration_pattern
  : type simple_designation
  ;
```

The runtime semantic of this expression is that it tests the runtime type of the left-hand *relational_expression* operand against the *type* in the pattern. If it is of that runtime type (or some subtype), the result of the `is operator` is `true`. It declares a new local variable named by the *identifier* that is assigned the value of the left-hand operand when the result is `true`.

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern compatible* with the type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`. It is a compile-time error if an expression of type `E` is not pattern compatible with the type in a type pattern that it is matched with.

Note: In C# 7.1 we extend this to permit a pattern-matching operation if either the input type or the type `T` is an open type. This paragraph is replaced by the following:

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern compatible* with the type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`, or if either `E` or `T` is an open type. It is a compile-time error if an expression of type `E` is not pattern compatible with the type in a type pattern that it is matched with.

The declaration pattern is useful for performing run-time type tests of reference types, and replaces the idiom

```
C#
```

```
var v = expr as Type;  
if (v != null) { // code using v }
```

With the slightly more concise

```
C#
```

```
if (expr is Type v) { // code using v }
```

It is an error if *type* is a nullable value type.

The declaration pattern can be used to test values of nullable types: a value of type `Nullable<T>` (or a boxed `T`) matches a type pattern `T2 id` if the value is non-null and the type of `T2` is `T`, or some base type or interface of `T`. For example, in the code fragment

```
C#
```

```
int? x = 3;
if (x is int v) { // code using v }
```

The condition of the `if` statement is `true` at runtime and the variable `v` holds the value `3` of type `int` inside the block.

Constant pattern

antlr

```
constant_pattern
    : shift_expression
    ;
```

A constant pattern tests the value of an expression against a constant value. The constant may be any constant expression, such as a literal, the name of a declared `const` variable, or an enumeration constant, or a `typeof` expression.

If both e and c are of integral types, the pattern is considered matched if the result of the expression `e == c` is `true`.

Otherwise the pattern is considered matching if `object.Equals(e, c)` returns `true`. In this case it is a compile-time error if the static type of e is not *pattern compatible* with the type of the constant.

Var pattern

antlr

```
var_pattern
    : 'var' simple_designation
    ;
```

An expression e matches a *var_pattern* always. In other words, a match to a *var pattern* always succeeds. If the *simple_designation* is an identifier, then at runtime the value of e is bound to a newly introduced local variable. The type of the local variable is the static type of e .

It is an error if the name `var` binds to a type.

Switch statement

The `switch` statement is extended to select for execution the first block having an associated pattern that matches the *switch expression*.

```
antlr
```

```
switch_label
  : 'case' complex_pattern case_guard? ':'
  | 'case' constant_expression case_guard? ':'
  | 'default' ':'
  ;

case_guard
  : 'when' expression
  ;
```

The order in which patterns are matched is not defined. A compiler is permitted to match patterns out of order, and to reuse the results of already matched patterns to compute the result of matching of other patterns.

If a *case-guard* is present, its expression is of type `bool`. It is evaluated as an additional condition that must be satisfied for the case to be considered satisfied.

It is an error if a *switch_label* can have no effect at runtime because its pattern is subsumed by previous cases. [TODO: We should be more precise about the techniques the compiler is required to use to reach this judgment.]

A pattern variable declared in a *switch_label* is definitely assigned in its case block if and only if that case block contains precisely one *switch_label*.

[TODO: We should specify when a *switch block* is reachable.]

Scope of pattern variables

The scope of a variable declared in a pattern is as follows:

- If the pattern is a case label, then the scope of the variable is the *case block*.

Otherwise the variable is declared in an *is_pattern* expression, and its scope is based on the construct immediately enclosing the expression containing the *is_pattern* expression as follows:

- If the expression is in an expression-bodied lambda, its scope is the body of the lambda.
- If the expression is in an expression-bodied method or property, its scope is the body of the method or property.

- If the expression is in a `when` clause of a `catch` clause, its scope is that `catch` clause.
- If the expression is in an *iteration_statement*, its scope is just that statement.
- Otherwise if the expression is in some other statement form, its scope is the scope containing the statement.

For the purpose of determining the scope, an *embedded_statement* is considered to be in its own scope. For example, the grammar for an *if_statement* is

```
antlr
if_statement
    : 'if' '(' boolean_expression ')' embedded_statement
    | 'if' '(' boolean_expression ')' embedded_statement 'else'
embedded_statement
    ;
```

So if the controlled statement of an *if_statement* declares a pattern variable, its scope is restricted to that *embedded_statement*:

```
C#
if (x) M(y is var z);
```

In this case the scope of `z` is the embedded statement `M(y is var z);`.

Other cases are errors for other reasons (e.g. in a parameter's default value or an attribute, both of which are an error because those contexts require a constant expression).

In [C# 7.3](#) we added the following contexts in which a pattern variable may be declared:

- If the expression is in a *constructor initializer*, its scope is the *constructor initializer* and the constructor's body.
- If the expression is in a field initializer, its scope is the *equals_value_clause* in which it appears.
- If the expression is in a query clause that is specified to be translated into the body of a lambda, its scope is just that expression.

Changes to syntactic disambiguation

There are situations involving generics where the C# grammar is ambiguous, and the language spec says how to resolve those ambiguities:

7.6.5.2 Grammar ambiguities

The productions for *simple-name* (§7.6.3) and *member-access* (§7.6.5) can give rise to ambiguities in the grammar for expressions. For example, the statement:

```
C#  
F(G<A,B>(7));
```

could be interpreted as a call to `F` with two arguments, `G < A` and `B > (7)`. Alternatively, it could be interpreted as a call to `F` with one argument, which is a call to a generic method `G` with two type arguments and one regular argument.

If a sequence of tokens can be parsed (in context) as a *simple-name* (§7.6.3), *member-access* (§7.6.5), or *pointer-member-access* (§18.5.2) ending with a *type-argument-list* (§4.4.1), the token immediately following the closing `>` token is examined. If it is one of

```
none  
  
( ) ] } : ; , . ? == != | ^
```

then the *type-argument-list* is retained as part of the *simple-name*, *member-access* or *pointer-member-access* and any other possible parse of the sequence of tokens is discarded. Otherwise, the *type-argument-list* is not considered to be part of the *simple-name*, *member-access* or `>` *pointer-member-access*, even if there is no other possible parse of the sequence of tokens. Note that these rules are not applied when parsing a *type-argument-list* in a *namespace-or-type-name* (§3.8). The statement

```
C#  
F(G<A,B>(7));
```

will, according to this rule, be interpreted as a call to `F` with one argument, which is a call to a generic method `G` with two type arguments and one regular argument.

The statements

```
C#
```

```
F(G < A, B > 7);  
F(G < A, B >> 7);
```

will each be interpreted as a call to `F` with two arguments. The statement

```
C#
```

```
x = F < A > +y;
```

will be interpreted as a less than operator, greater than operator, and unary plus operator, as if the statement had been written `x = (F < A) > (+y)`, instead of as a *simple-name* with a *type-argument-list* followed by a binary plus operator. In the statement

```
C#
```

```
x = y is C<T> + z;
```

the tokens `C<T>` are interpreted as a *namespace-or-type-name* with a *type-argument-list*.

There are a number of changes being introduced in C# 7 that make these disambiguation rules no longer sufficient to handle the complexity of the language.

Out variable declarations

It is now possible to declare a variable in an out argument:

```
C#
```

```
M(out Type name);
```

However, the type may be generic:

```
C#
```

```
M(out A<B> name);
```

Since the language grammar for the argument uses *expression*, this context is subject to the disambiguation rule. In this case the closing `>` is followed by an *identifier*, which is

not one of the tokens that permits it to be treated as a *type-argument-list*. I therefore propose to add *identifier* to the set of tokens that triggers the disambiguation to a *type-argument-list*.

Tuples and deconstruction declarations

A tuple literal runs into exactly the same issue. Consider the tuple expression

```
C#  
  
(A < B, C > D, E < F, G > H)
```

Under the old C# 6 rules for parsing an argument list, this would parse as a tuple with four elements, starting with `A < B` as the first. However, when this appears on the left of a deconstruction, we want the disambiguation triggered by the *identifier* token as described above:

```
C#  
  
(A<B,C> D, E<F,G> H) = e;
```

This is a deconstruction declaration which declares two variables, the first of which is of type `A<B,C>` and named `D`. In other words, the tuple literal contains two expressions, each of which is a declaration expression.

For simplicity of the specification and compiler, I propose that this tuple literal be parsed as a two-element tuple wherever it appears (whether or not it appears on the left-hand-side of an assignment). That would be a natural result of the disambiguation described in the previous section.

Pattern-matching

Pattern matching introduces a new context where the expression-type ambiguity arises. Previously the right-hand-side of an `is` operator was a type. Now it can be a type or expression, and if it is a type it may be followed by an identifier. This can, technically, change the meaning of existing code:

```
C#  
  
var x = e is T < A > B;
```

This could be parsed under C#6 rules as

```
C#
```

```
var x = ((e is T) < A) > B;
```

but under under C#7 rules (with the disambiguation proposed above) would be parsed as

```
C#
```

```
var x = e is T<A> B;
```

which declares a variable `B` of type `T<A>`. Fortunately, the native and Roslyn compilers have a bug whereby they give a syntax error on the C#6 code. Therefore this particular breaking change is not a concern.

Pattern-matching introduces additional tokens that should drive the ambiguity resolution toward selecting a type. The following examples of existing valid C#6 code would be broken without additional disambiguation rules:

```
C#
```

```
var x = e is A<B> && f;           // &&  
var x = e is A<B> || f;          // ||  
var x = e is A<B> & f;           // &  
var x = e is A<B>[];            // [  

```

Proposed change to the disambiguation rule

I propose to revise the specification to change the list of disambiguating tokens from

```
none
```

```
( ) ] } : ; , . ? == != | ^
```

to

```
none
```

```
( ) ] } : ; , . ? == != | ^ && || & [  

```

And, in certain contexts, we treat *identifier* as a disambiguating token. Those contexts are where the sequence of tokens being disambiguated is immediately preceded by one

of the keywords `is`, `case`, or `out`, or arises while parsing the first element of a tuple literal (in which case the tokens are preceded by `(` or `:` and the identifier is followed by a `,`) or a subsequent element of a tuple literal.

Modified disambiguation rule

The revised disambiguation rule would be something like this

If a sequence of tokens can be parsed (in context) as a *simple-name* (§7.6.3), *member-access* (§7.6.5), or *pointer-member-access* (§18.5.2) ending with a *type-argument-list* (§4.4.1), the token immediately following the closing `>` token is examined, to see if it is

- One of `()] } : ; , . ? == != | ^ && || & [`; or
- One of the relational operators `< > <= >= is as`; or
- A contextual query keyword appearing inside a query expression; or
- In certain contexts, we treat *identifier* as a disambiguating token. Those contexts are where the sequence of tokens being disambiguated is immediately preceded by one of the keywords `is`, `case` or `out`, or arises while parsing the first element of a tuple literal (in which case the tokens are preceded by `(` or `:` and the identifier is followed by a `,`) or a subsequent element of a tuple literal.

If the following token is among this list, or an identifier in such a context, then the *type-argument-list* is retained as part of the *simple-name*, *member-access* or *pointer-member-access* and any other possible parse of the sequence of tokens is discarded. Otherwise, the *type-argument-list* is not considered to be part of the *simple-name*, *member-access* or *pointer-member-access*, even if there is no other possible parse of the sequence of tokens. Note that these rules are not applied when parsing a *type-argument-list* in a *namespace-or-type-name* (§3.8).

Breaking changes due to this proposal

No breaking changes are known due to this proposed disambiguation rule.

Interesting examples

Here are some interesting results of these disambiguation rules:

The expression `(A < B, C > D)` is a tuple with two elements, each a comparison.

The expression `(A<B,C> D, E)` is a tuple with two elements, the first of which is a declaration expression.

The invocation `M(A < B, C > D, E)` has three arguments.

The invocation `M(out A<B,C> D, E)` has two arguments, the first of which is an `out` declaration.

The expression `e is A C` uses a declaration expression.

The case label `case A C:` uses a declaration expression.

Some examples of pattern matching

Is-As

We can replace the idiom

```
C#  
  
var v = expr as Type;  
if (v != null) {  
    // code using v  
}
```

With the slightly more concise and direct

```
C#  
  
if (expr is Type v) {  
    // code using v  
}
```

Testing nullable

We can replace the idiom

```
C#  
  
Type? v = x?.y?.z;  
if (v.HasValue) {  
    var value = v.GetValueOrDefault();  
    // code using value  
}
```

With the slightly more concise and direct

```
C#  
  
if (x?.y?.z is Type value) {  
    // code using value  
}
```

Arithmetic simplification

Suppose we define a set of recursive types to represent expressions (per a separate proposal):

```
C#  
  
abstract class Expr;  
class X() : Expr;  
class Const(double Value) : Expr;  
class Add(Expr Left, Expr Right) : Expr;  
class Mult(Expr Left, Expr Right) : Expr;  
class Neg(Expr Value) : Expr;
```

Now we can define a function to compute the (unreduced) derivative of an expression:

```
C#  
  
Expr Deriv(Expr e)  
{  
    switch (e) {  
        case X(): return Const(1);  
        case Const(*): return Const(0);  
        case Add(var Left, var Right):  
            return Add(Deriv(Left), Deriv(Right));  
        case Mult(var Left, var Right):  
            return Add(Mult(Deriv(Left), Right), Mult(Left, Deriv(Right)));  
        case Neg(var Value):  
            return Neg(Deriv(Value));  
    }  
}
```

An expression simplifier demonstrates positional patterns:

```
C#  
  
Expr Simplify(Expr e)  
{  
    switch (e) {  
        case Mult(Const(0), *): return Const(0);  
    }  
}
```

```
case Mult(*, Const(0)): return Const(0);
case Mult(Const(1), var x): return Simplify(x);
case Mult(var x, Const(1)): return Simplify(x);
case Mult(Const(var l), Const(var r)): return Const(l*r);
case Add(Const(0), var x): return Simplify(x);
case Add(var x, Const(0)): return Simplify(x);
case Add(Const(var l), Const(var r)): return Const(l+r);
case Neg(Const(var k)): return Const(-k);
default: return e;
}
}
```

Out variable declarations

Article • 2021-09-21 • 2 minutes to read

The *out variable declaration* feature enables a variable to be declared at the location that it is being passed as an `out` argument.

```
antlr
```

```
argument_value
  : 'out' type identifier
  | ...
  ;
```

A variable declared this way is called an *out variable*. You may use the contextual keyword `var` for the variable's type. The scope will be the same as for a *pattern-variable* introduced via pattern-matching.

According to Language Specification (section 7.6.7 Element access) the argument-list of an element-access (indexing expression) does not contain `ref` or `out` arguments.

However, they are permitted by the compiler for various scenarios, for example indexers declared in metadata that accept `out`.

Within the scope of a local variable introduced by an `argument_value`, it is a compile-time error to refer to that local variable in a textual position that precedes its declaration.

It is also an error to reference an implicitly-typed (§8.5.1) `out` variable in the same argument list that immediately contains its declaration.

Overload resolution is modified as follows:

We add a new conversion:

There is a *conversion from expression* from an implicitly-typed `out` variable declaration to every type.

Also

The type of an explicitly-typed `out` variable argument is the declared type.

and

An implicitly-typed `out` variable argument has no type.

The *conversion from expression* from an implicitly-typed out variable declaration is not considered better than any other *conversion from expression*.

The type of an implicitly-typed out variable is the type of the corresponding parameter in the signature of the method selected by overload resolution.

The new syntax node `DeclarationExpressionSyntax` is added to represent the declaration in an out var argument.

Async Task Types in C#

Article • 2021-10-13 • 3 minutes to read

Extend `async` to support *task types* that match a specific pattern, in addition to the well known types `System.Threading.Tasks.Task` and `System.Threading.Tasks.Task<T>`.

Task Type

A *task type* is a `class` or `struct` with an associated *builder type* identified with `System.Runtime.CompilerServices.AsyncMethodBuilderAttribute`. The *task type* may be non-generic, for async methods that do not return a value, or generic, for methods that return a value.

To support `await`, the *task type* must have a corresponding, accessible `GetAwaiter()` method that returns an instance of an *awaiter type* (see [C# 7.7.7.1 Awaitable expressions](#)).

```
C#

[AsyncMethodBuilder(typeof(MyTaskMethodBuilder<>))]
class MyTask<T>
{
    public Awaiter<T> GetAwaiter();
}

class Awaiter<T> : INotifyCompletion
{
    public bool IsCompleted { get; }
    public T GetResult();
    public void OnCompleted(Action completion);
}
```

Builder Type

The *builder type* is a `class` or `struct` that corresponds to the specific *task type*. The *builder type* can have at most 1 type parameter and must not be nested in a generic type. The *builder type* has the following `public` methods. For non-generic *builder types*, `SetResult()` has no parameters.

```
C#

class MyTaskMethodBuilder<T>
{
```

```

public static MyTaskMethodBuilder<T> Create();

public void Start<TStateMachine>(ref TStateMachine stateMachine)
    where TStateMachine : IAsyncStateMachine;

public void SetStateMachine(IAsyncStateMachine stateMachine);
public void SetException(Exception exception);
public void SetResult(T result);

public void AwaitOnCompleted<TAwaiter, TStateMachine>(
    ref TAwaiter awaiter, ref TStateMachine stateMachine)
    where TAwaiter : INotifyCompletion
    where TStateMachine : IAsyncStateMachine;
public void AwaitUnsafeOnCompleted<TAwaiter, TStateMachine>(
    ref TAwaiter awaiter, ref TStateMachine stateMachine)
    where TAwaiter : ICriticalNotifyCompletion
    where TStateMachine : IAsyncStateMachine;

public MyTask<T> Task { get; }
}

```

Execution

The types above are used by the compiler to generate the code for the state machine of an `async` method. (The generated code is equivalent to the code generated for `async` methods that return `Task`, `Task<T>`, or `void`. The difference is, for those well known types, the *builder types* are also known to the compiler.)

`Builder.Create()` is invoked to create an instance of the *builder type*.

`builder.Start(ref stateMachine)` is invoked to associate the builder with compiler-generated state machine instance. The builder must call `stateMachine.MoveNext()` either in `Start()` or after `Start()` has returned to advance the state machine. After `Start()` returns, the `async` method calls `builder.Task` for the task to return from the `async` method.

Each call to `stateMachine.MoveNext()` will advance the state machine. If the state machine completes successfully, `builder.SetResult()` is called, with the method return value if any. If an exception is thrown in the state machine, `builder.SetException(exception)` is called.

If the state machine reaches an `await expr` expression, `expr.GetAwaiter()` is invoked. If the awaiter implements `ICriticalNotifyCompletion` and `IsCompleted` is false, the state machine invokes `builder.AwaitUnsafeOnCompleted(ref awaiter, ref stateMachine)`. `AwaitUnsafeOnCompleted()` should call `awaiter.UnsafeOnCompleted(action)` with an

`Action` that calls `stateMachine.MoveNext()` when the awaiter completes. Similarly for `INotifyCompletion` and `builder.AwaitOnCompleted()`.

`SetStateMachine(IAsyncStateMachine)` is called by the compiler-generated `IAsyncStateMachine` implementation. That can be used to identify the instance of the builder associated with a state machine instance, particularly for cases where the state machine is implemented as a value type: if the builder calls `stateMachine.SetStateMachine(stateMachine)`, the `stateMachine` will call `builder.SetStateMachine(stateMachine)` on the *builder instance associated with stateMachine*.

Overload Resolution

Overload resolution is extended to recognize *task types* in addition to `Task` and `Task<T>`.

An `async` lambda with no return value is an exact match for an overload candidate parameter of non-generic *task type*, and an `async` lambda with return type `T` is an exact match for an overload candidate parameter of generic *task type*.

Otherwise if an `async` lambda is not an exact match for either of two candidate parameters of *task types*, or an exact match for both, and there is an implicit conversion from one candidate type to the other, the from candidate wins. Otherwise recursively evaluate the types `A` and `B` within `Task1<A>` and `Task2` for better match.

Otherwise if an `async` lambda is not an exact match for either of two candidate parameters of *task types*, but one candidate is a more specialized type than the other, the more specialized candidate wins.

Infer tuple names (aka. tuple projection initializers)

Article • 2021-09-21 • 2 minutes to read

Summary

In a number of common cases, this feature allows the tuple element names to be omitted and instead be inferred. For instance, instead of typing `(f1: x.f1, f2: x?.f2)`, the element names "f1" and "f2" can be inferred from `(x.f1, x?.f2)`.

This parallels the behavior of anonymous types, which allow inferring member names during creation. For instance, `new { x.f1, y?.f2 }` declares members "f1" and "f2".

This is particularly handy when using tuples in LINQ:

```
C#
```

```
// "c" and "result" have element names "f1" and "f2"  
var result = list.Select(c => (c.f1, c.f2)).Where(t => t.f2 == 1);
```

Detailed design

There are two parts to the change:

1. Try to infer a candidate name for each tuple element which does not have an explicit name:
 - Using same rules as name inference for anonymous types.
 - In C#, this allows three cases: `y` (identifier), `x.y` (simple member access) and `x?.y` (conditional access).
 - In VB, this allows for additional cases, such as `x.y()`.
 - Rejecting reserved tuple names (case-sensitive in C#, case-insensitive in VB), as they are either forbidden or already implicit. For instance, such as `ItemN`, `Rest`, and `ToString`.
 - If any candidate names are duplicates (case-sensitive in C#, case-insensitive in VB) within the entire tuple, we drop those candidates,
2. During conversions (which check and warn about dropping names from tuple literals), inferred names would not produce any warnings. This avoids breaking

existing tuple code.

Note that the rule for handling duplicates is different than that for anonymous types. For instance, `new { x.f1, x.f1 }` produces an error, but `(x.f1, x.f1)` would still be allowed (just without any inferred names). This avoids breaking existing tuple code.

For consistency, the same would apply to tuples produced by deconstruction-assignments (in C#):

```
C#  
  
// tuple has element names "f1" and "f2"  
var tuple = ((x.f1, x?.f2) = (1, 2));
```

The same would also apply to VB tuples, using the VB-specific rules for inferring name from expression and case-insensitive name comparisons.

When using the C# 7.1 compiler (or later) with language version "7.0", the element names will be inferred (despite the feature not being available), but there will be a use-site error for trying to access them. This will limit additions of new code that would later face the compatibility issue (described below).

Drawbacks

The main drawback is that this introduces a compatibility break from C# 7.0:

```
C#  
  
Action y = () => M();  
var t = (x: x, y);  
t.y(); // this might have previously picked up an extension method called  
"y", but would now call the lambda.
```

The compatibility council found this break acceptable, given that it is limited and the time window since tuples shipped (in C# 7.0) is short.

pattern-matching with generics

Article • 2022-02-23 • 2 minutes to read

Summary

The specification for the existing C# as operator (§11.11.12) permits there to be no conversion between the type of the operand and the specified type when either is an open type. However, in C# 7 the `Type identifier` pattern requires there be a conversion between the type of the input and the given type.

We propose to relax this and change `expression is Type identifier`, in addition to being permitted in the conditions when it is permitted in C# 7, to also be permitted when `expression as Type` would be allowed. Specifically, the new cases are cases where the type of the expression or the specified type is an open type.

Motivation

Cases where pattern-matching should "obviously" be permitted currently fail to compile. See, for example, <https://github.com/dotnet/roslyn/issues/16195>.

Detailed design

We change the paragraph in the pattern-matching specification (the proposed addition is shown in bold):

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern compatible* with the type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`, **or if either `E` or `T` is an open type**. It is a compile-time error if an expression of type `E` is not pattern compatible with the type in a type pattern that it is matched with.

Drawbacks

None.

Alternatives

None.

Unresolved questions

None.

Design meetings

LDM considered this question and felt it was a bug-fix level change. We are treating it as a separate language feature because just making the change after the language has been released would introduce a forward incompatibility. Using the proposed change requires that the programmer specify language version 7.1.

Readonly references

Article • 2021-10-13 • 24 minutes to read

Summary

The "readonly references" feature is actually a group of features that leverage the efficiency of passing variables by reference, but without exposing the data to modifications:

- `in` parameters
- `ref readonly` returns
- `readonly` structs
- `ref/in` extension methods
- `ref readonly` locals
- `ref` conditional expressions

Passing arguments as readonly references.

There is an existing proposal that touches this topic

<https://github.com/dotnet/roslyn/issues/115> as a special case of readonly parameters without going into many details. Here I just want to acknowledge that the idea by itself is not very new.

Motivation

Prior to this feature C# did not have an efficient way of expressing a desire to pass struct variables into method calls for readonly purposes with no intention of modifying. Regular by-value argument passing implies copying, which adds unnecessary costs. That drives users to use by-ref argument passing and rely on comments/documentation to indicate that the data is not supposed to be mutated by the callee. It is not a good solution for many reasons.

The examples are numerous - vector/matrix math operators in graphics libraries like [XNA](#) are known to have ref operands purely because of performance considerations. There is code in Roslyn compiler itself that uses structs to avoid allocations and then passes them by reference to avoid copying costs.

Solution (`in` parameters)

Similarly to the `out` parameters, `in` parameters are passed as managed references with additional guarantees from the callee.

Unlike `out` parameters which *must* be assigned by the callee before any other use, `in` parameters cannot be assigned by the callee at all.

As a result `in` parameters allow for effectiveness of indirect argument passing without exposing arguments to mutations by the callee.

Declaring `in` parameters

`in` parameters are declared by using `in` keyword as a modifier in the parameter signature.

For all purposes the `in` parameter is treated as a `readonly` variable. Most of the restrictions on the use of `in` parameters inside the method are the same as with `readonly` fields.

Indeed an `in` parameter may represent a `readonly` field. Similarity of restrictions is not a coincidence.

For example fields of an `in` parameter which has a struct type are all recursively classified as `readonly` variables .

C#

```
static Vector3 Add (in Vector3 v1, in Vector3 v2)
{
    // not OK!!
    v1 = default(Vector3);

    // not OK!!
    v1.X = 0;

    // not OK!!
    foo(ref v1.X);

    // OK
    return new Vector3(v1.X + v2.X, v1.Y + v2.Y, v1.Z + v2.Z);
}
```

- `in` parameters are allowed anywhere where ordinary `byval` parameters are allowed. This includes indexers, operators (including conversions), delegates, lambdas, local functions.

C#

```
(in int x) => x //  
lambda expression  
TValue this[in TKey index]; //  
indexer  
public static Vector3 operator +(in Vector3 x, in Vector3 y) => ... //  
operator
```

- `in` is not allowed in combination with `out` or with anything that `out` does not combine with.
- It is not permitted to overload on `ref/out/in` differences.
- It is permitted to overload on ordinary byval and `in` differences.
- For the purpose of OHI (Overloading, Hiding, Implementing), `in` behaves similarly to an `out` parameter. All the same rules apply. For example the overriding method will have to match `in` parameters with `in` parameters of an identity-convertible type.
- For the purpose of delegate/lambda/method group conversions, `in` behaves similarly to an `out` parameter. Lambdas and applicable method group conversion candidates will have to match `in` parameters of the target delegate with `in` parameters of an identity-convertible type.
- For the purpose of generic variance, `in` parameters are nonvariant.

NOTE: There are no warnings on `in` parameters that have reference or primitives types. It may be pointless in general, but in some cases user must/want to pass primitives as `in`. Examples - overriding a generic method like `Method(in T param)` when `T` was substituted to be `int`, or when having methods like `Volatile.Read(in int location)`

It is conceivable to have an analyzer that warns in cases of inefficient use of `in` parameters, but the rules for such analysis would be too fuzzy to be a part of a language specification.

Use of `in` at call sites. (`in` arguments)

There are two ways to pass arguments to `in` parameters.

in arguments can match in parameters:

An argument with an `in` modifier at the call site can match `in` parameters.

C#

```
int x = 1;

void M1<T>(in T x)
{
    // . . .
}

var x = M1(in x); // in argument to a method

class D
{
    public string this[in Guid index];
}

D dictionary = . . . ;
var y = dictionary[in Guid.Empty]; // in argument to an indexer
```

- `in` argument must be a *readable* LValue(*). Example: `M1(in 42)` is invalid

(*) The notion of [LValue/RValue](#) vary between languages.

Here, by LValue I mean an expression that represent a location that can be referred to directly. And RValue means an expression that yields a temporary result which does not persist on its own.

- In particular it is valid to pass `readonly` fields, `in` parameters or other formally `readonly` variables as `in` arguments. Example: `dictionary[in Guid.Empty]` is legal. `Guid.Empty` is a static `readonly` field.
- `in` argument must have type *identity-convertible* to the type of the parameter. Example: `M1<object>(in Guid.Empty)` is invalid. `Guid.Empty` is not *identity-convertible* to `object`

The motivation for the above rules is that `in` arguments guarantee *aliasing* of the argument variable. The callee always receives a direct reference to the same location as represented by the argument.

- in rare situations when `in` arguments must be stack-spilled due to `await` expressions used as operands of the same call, the behavior is the same as with

`out` and `ref` arguments - if the variable cannot be spilled in referentially-transparent manner, an error is reported.

Examples:

1. `M1(in staticField, await SomethingAsync())` is valid. `staticField` is a static field which can be accessed more than once without observable side effects. Therefore both the order of side effects and aliasing requirements can be provided.
2. `M1(in RefReturningMethod(), await SomethingAsync())` will produce an error. `RefReturningMethod()` is a `ref` returning method. A method call may have observable side effects, therefore it must be evaluated before the `SomethingAsync()` operand. However the result of the invocation is a reference that cannot be preserved across the `await` suspension point which make the direct reference requirement impossible.

NOTE: the stack spilling errors are considered to be implementation-specific limitations. Therefore they do not have effect on overload resolution or lambda inference.

Ordinary byval arguments can match `in` parameters:

Regular arguments without modifiers can match `in` parameters. In such case the arguments have the same relaxed constraints as an ordinary byval arguments would have.

The motivation for this scenario is that `in` parameters in APIs may result in inconveniences for the user when arguments cannot be passed as a direct reference - ex: literals, computed or `await`-ed results or arguments that happen to have more specific types.

All these cases have a trivial solution of storing the argument value in a temporary local of appropriate type and passing that local as an `in` argument.

To reduce the need for such boilerplate code compiler can perform the same transformation, if needed, when `in` modifier is not present at the call site.

In addition, in some cases, such as invocation of operators, or `in` extension methods, there is no syntactical way to specify `in` at all. That alone requires specifying the behavior of ordinary byval arguments when they match `in` parameters.

In particular:

- it is valid to pass RValues. A reference to a temporary is passed in such case.
Example:

```
C#
```

```
Print("hello");    // not an error.  
  
void Print<T>(in T x)  
{  
    // . . .  
}
```

- implicit conversions are allowed.

This is actually a special case of passing an RValue

A reference to a temporary holding converted value is passed in such case. Example:

```
C#
```

```
Print<int>(Short.MaxValue)    // not an error.
```

- in a case of a receiver of an `in` extension method (as opposed to `ref` extension methods), RValues or implicit *this-argument-conversions* are allowed. A reference to a temporary holding converted value is passed in such case. Example:

```
C#
```

```
public static IEnumerable<T> Concat<T>(in this (IEnumerable<T>,  
IEnumerable<T>) arg) => . . . ;  
  
("aa", "bb").Concat<char>()    // not an error.
```

More information on `ref/in` extension methods is provided further in this document.

- argument spilling due to `await` operands could spill "by-value", if necessary. In scenarios where providing a direct reference to the argument is not possible due to intervening `await` a copy of the argument's value is spilled instead.

Example:

```
C#
```

```
M1(RefReturningMethod(), await SomethingAsync())    // not an error.
```

Since the result of a side-effecting invocation is a reference that cannot be preserved across `await` suspension, a temporary containing the actual value will be preserved instead (as it would in an ordinary `byval` parameter case).

Omitted optional arguments

It is permitted for an `in` parameter to specify a default value. That makes the corresponding argument optional.

Omitting optional argument at the call site results in passing the default value via a temporary.

```
C#  
  
Print("hello");           // not an error, same as  
Print("hello", c: Color.Black);  
  
void Print(string s, in Color c = Color.Black)  
{  
    // . . .  
}
```

Aliasing behavior in general

Just like `ref` and `out` variables, `in` variables are references/aliases to existing locations.

While callee is not allowed to write into them, reading an `in` parameter can observe different values as a side effect of other evaluations.

Example:

```
C#  
  
static Vector3 v = Vector3.UnitY;  
  
static void Main()  
{  
    Test(v);  
}  
  
static void Test(in Vector3 v1)  
{  
    Debug.Assert(v1 == Vector3.UnitY);  
    // changes v1 deterministically (no races required)  
    ChangeV();  
    Debug.Assert(v1 == Vector3.UnitX);  
}  
  
static void ChangeV()  
{  
    v = Vector3.UnitX;  
}
```

in parameters and capturing of local variables.

For the purpose of lambda/async capturing `in` parameters behave the same as `out` and `ref` parameters.

- `in` parameters cannot be captured in a closure
- `in` parameters are not allowed in iterator methods
- `in` parameters are not allowed in async methods

Temporary variables.

Some uses of `in` parameter passing may require indirect use of a temporary local variable:

- `in` arguments are always passed as direct aliases when call-site uses `in`. Temporary is never used in such case.
- `in` arguments are not required to be direct aliases when call-site does not use `in`. When argument is not an LValue, a temporary may be used.
- `in` parameter may have default value. When corresponding argument is omitted at the call site, the default value are passed via a temporary.
- `in` arguments may have implicit conversions, including those that do not preserve identity. A temporary is used in those cases.
- receivers of ordinary struct calls may not be writable LValues (**existing case!**). A temporary is used in those cases.

The life time of the argument temporaries matches the closest encompassing scope of the call-site.

The formal life time of temporary variables is semantically significant in scenarios involving escape analysis of variables returned by reference.

Metadata representation of `in` parameters.

When `System.Runtime.CompilerServices.IsReadOnlyAttribute` is applied to a byref parameter, it means that the parameter is an `in` parameter.

In addition, if the method is *abstract* or *virtual*, then the signature of such parameters (and only such parameters) must have

```
modreq[System.Runtime.InteropServices.InAttribute].
```

Motivation: this is done to ensure that in a case of method overriding/implementing the `in` parameters match.

Same requirements apply to `Invoke` methods in delegates.

Motivation: this is to ensure that existing compilers cannot simply ignore `readonly` when creating or assigning delegates.

Returning by readonly reference.

Motivation

The motivation for this sub-feature is roughly symmetrical to the reasons for the `in` parameters - avoiding copying, but on the returning side. Prior to this feature, a method or an indexer had two options: 1) return by reference and be exposed to possible mutations or 2) return by value which results in copying.

Solution (`ref readonly` returns)

The feature allows a member to return variables by reference without exposing them to mutations.

Declaring `ref readonly` returning members

A combination of modifiers `ref readonly` on the return signature is used to indicate that the member returns a readonly reference.

For all purposes a `ref readonly` member is treated as a `readonly` variable - similar to `readonly` fields and `in` parameters.

For example fields of `ref readonly` member which has a struct type are all recursively classified as `readonly` variables. - It is permitted to pass them as `in` arguments, but not as `ref` or `out` arguments.

C#

```
ref readonly Guid Method1()
{
}

Method2(in Method1()); // valid. Can pass as `in` argument.

Method3(ref Method1()); // not valid. Cannot pass as `ref` argument
```

- `ref readonly` returns are allowed in the same places where `ref` returns are allowed. This includes indexers, delegates, lambdas, local functions.
- It is not permitted to overload on `ref/ref readonly` / differences.
- It is permitted to overload on ordinary byval and `ref readonly` return differences.
- For the purpose of OHI (Overloading, Hiding, Implementing), `ref readonly` is similar but distinct from `ref`. For example the a method that overrides `ref readonly` one, must itself be `ref readonly` and have identity-convertible type.
- For the purpose of delegate/lambda/method group conversions, `ref readonly` is similar but distinct from `ref`. Lambdas and applicable method group conversion candidates have to match `ref readonly` return of the target delegate with `ref readonly` return of the type that is identity-convertible.
- For the purpose of generic variance, `ref readonly` returns are nonvariant.

NOTE: There are no warnings on `ref readonly` returns that have reference or primitive types. It may be pointless in general, but in some cases user must/want to pass primitives as `in`. Examples - overriding a generic method like `ref readonly T Method()` when `T` was substituted to be `int`.

It is conceivable to have an analyzer that warns in cases of inefficient use of `ref readonly` returns, but the rules for such analysis would be too fuzzy to be a part of a language specification.

Returning from `ref readonly` members

Inside the method body the syntax is the same as with regular `ref` returns. The `readonly` will be inferred from the containing method.

The motivation is that `return ref readonly <expression>` is unnecessary long and only allows for mismatches on the `readonly` part that would always result in errors. The `ref` is, however, required for consistency with other scenarios where something is passed via strict aliasing vs. by value.

Unlike the case with `in` parameters, `ref readonly` returns never return via a local copy. Considering that the copy would cease to exist immediately upon returning such practice would be pointless and dangerous. Therefore `ref readonly` returns are always direct references.

Example:

```
C#  
  
struct ImmutableArray<T>  
{  
    private readonly T[] array;  
  
    public ref readonly T ItemRef(int i)  
    {  
        // returning a readonly reference to an array element  
        return ref this.array[i];  
    }  
}
```

- An argument of `return ref` must be an LValue (**existing rule**)
- An argument of `return ref` must be "safe to return" (**existing rule**)
- In a `ref readonly` member an argument of `return ref` is *not required to be writeable*. For example such member can ref-return a readonly field or one of its `in` parameters.

Safe to Return rules.

Normal safe to return rules for references will apply to readonly references as well.

Note that a `ref readonly` can be obtained from a regular `ref` local/parameter/return, but not the other way around. Otherwise the safety of `ref readonly` returns is inferred the same way as for regular `ref` returns.

Considering that RValues can be passed as `in` parameter and returned as `ref readonly` we need one more rule - **RValues are not safe-to-return by reference.**

Consider the situation when an RValue is passed to an `in` parameter via a copy and then returned back in a form of a `ref readonly`. In the context of the caller the result of such invocation is a reference to local data and as such is unsafe to return. Once RValues are not safe to return, the existing rule #6 already handles this case.

Example:

```
C#  
  
ref readonly Vector3 Test1()  
{  
    // can pass an RValue as "in" (via a temp copy)}
```

```

// but the result is not safe to return
// because the RValue argument was not safe to return by reference
return ref Test2(default(Vector3));
}

ref readonly Vector3 Test2(in Vector3 r)
{
    // this is ok, r is returnable
    return ref r;
}

```

Updated `safe to return` rules:

1. `refs` to variables on the heap are safe to return
2. `ref/in` parameters are safe to return `in` parameters naturally can only be returned as `readonly`.
3. `out` parameters are safe to return (but must be definitely assigned, as is already the case today)
4. instance struct fields are safe to return as long as the receiver is safe to return
5. `'this'` is not safe to return from struct members
6. a `ref`, returned from another method is safe to return if all `refs/outs` passed to that method as formal parameters were safe to return. *Specifically it is irrelevant if receiver is safe to return, regardless whether receiver is a struct, class or typed as a generic type parameter.*
7. `RValues` are not safe to return by reference. *Specifically RValues are safe to pass as in parameters.*

NOTE: There are additional rules regarding safety of returns that come into play when `ref-like` types and `ref-reassignments` are involved. The rules equally apply to `ref` and `ref readonly` members and therefore are not mentioned here.

Aliasing behavior.

`ref readonly` members provide the same aliasing behavior as ordinary `ref` members (except for being `readonly`). Therefore for the purpose of capturing in lambdas, `async`, iterators, stack spilling etc... the same restrictions apply. - I.E. due to inability to capture the actual references and due to side-effecting nature of member evaluation such scenarios are disallowed.

It is permitted and required to make a copy when `ref readonly` return is a receiver of regular struct methods, which take `this` as an ordinary writable reference. Historically in all cases where such invocations are applied to `readonly` variable a local copy is made.

Metadata representation.

When `System.Runtime.CompilerServices.IsReadOnlyAttribute` is applied to the return of a byref returning method, it means that the method returns a readonly reference.

In addition, the result signature of such methods (and only those methods) must have `modreq[System.Runtime.CompilerServices.IsReadOnlyAttribute]`.

Motivation: this is to ensure that existing compilers cannot simply ignore `readonly` when invoking methods with `ref readonly` returns

Readonly structs

In short - a feature that makes `this` parameter of all instance members of a struct, except for constructors, an `in` parameter.

Motivation

Compiler must assume that any method call on a struct instance may modify the instance. Indeed a writeable reference is passed to the method as `this` parameter and fully enables this behavior. To allow such invocations on `readonly` variables, the invocations are applied to temp copies. That could be unintuitive and sometimes forces people to abandon `readonly` for performance reasons.

Example: <https://codeblog.jonskeet.uk/2014/07/16/micro-optimization-the-surprising-inefficiency-of-readonly-fields/> ↗

After adding support for `in` parameters and `ref readonly` returns the problem of defensive copying will get worse since readonly variables will become more common.

Solution

Allow `readonly` modifier on struct declarations which would result in `this` being treated as `in` parameter on all struct instance methods except for constructors.

```
C#
```

```
static void Test(in Vector3 v1)
{
    // no need to make a copy of v1 since Vector3 is a readonly struct
    System.Console.WriteLine(v1.ToString());
}

readonly struct Vector3
```

```

{
    . . .

    public override string ToString()
    {
        // not OK!! `this` is an `in` parameter
        foo(ref this.X);

        // OK
        return $"X: {X}, Y: {Y}, Z: {Z}";
    }
}

```

Restrictions on members of readonly struct

- Instance fields of a readonly struct must be readonly.
Motivation: can only be written to externally, but not through members.
- Instance autoproperties of a readonly struct must be get-only.
Motivation: consequence of restriction on instance fields.
- Readonly struct may not declare field-like events.
Motivation: consequence of restriction on instance fields.

Metadata representation.

When `System.Runtime.CompilerServices.IsReadOnlyAttribute` is applied to a value type, it means that the type is a `readonly struct`.

In particular:

- The identity of the `IsReadOnlyAttribute` type is unimportant. In fact it can be embedded by the compiler in the containing assembly if needed.

ref/in extension methods

There is actually an existing proposal (<https://github.com/dotnet/roslyn/issues/165>) and corresponding prototype PR (<https://github.com/dotnet/roslyn/pull/15650>). I just want to acknowledge that this idea is not entirely new. It is, however, relevant here since `ref readonly` elegantly removes the most contentious issue about such methods - what to do with RValue receivers.

The general idea is allowing extension methods to take the `this` parameter by reference, as long as the type is known to be a struct type.

C#

```
public static void Extension(ref this Guid self)
{
    // do something
}
```

The reasons for writing such extension methods are primarily:

1. Avoid copying when receiver is a large struct
2. Allow mutating extension methods on structs

The reasons why we do not want to allow this on classes

1. It would be of very limited purpose.
2. It would break long standing invariant that a method call cannot turn non-`null` receiver to become `null` after invocation.

In fact, currently a non-`null` variable cannot become `null` unless *explicitly* assigned or passed by `ref` or `out`. That greatly aids readability or other forms of "can this be a null here" analysis. 3. It would be hard to reconcile with "evaluate once" semantics of null-conditional accesses. Example: `obj.stringField?.RefExtension(...)` - need to capture a copy of `stringField` to make the null check meaningful, but then assignments to `this` inside `RefExtension` would not be reflected back to the field.

An ability to declare extension methods on **structs** that take the first argument by reference was a long-standing request. One of the blocking consideration was "what happens if receiver is not an LValue?".

- There is a precedent that any extension method could also be called as a static method (sometimes it is the only way to resolve ambiguity). It would dictate that RValue receivers should be disallowed.
- On the other hand there is a practice of making invocation on a copy in similar situations when struct instance methods are involved.

The reason why the "implicit copying" exists is because the majority of struct methods do not actually modify the struct while not being able to indicate that. Therefore the most practical solution was to just make the invocation on a copy, but this practice is known for harming performance and causing bugs.

Now, with availability of `in` parameters, it is possible for an extension to signal the intent. Therefore the conundrum can be resolved by requiring `ref` extensions to be called with writable receivers while `in` extensions permit implicit copying if necessary.

C#

```
// this can be called on either RValue or an LValue
public static void Reader(in this Guid self)
{
    // do something nonmutating.
    WriteLine(self == default(Guid));
}

// this can be called only on an LValue
public static void Mutator(ref this Guid self)
{
    // can mutate self
    self = new Guid();
}
```

in extensions and generics.

The purpose of `ref` extension methods is to mutate the receiver directly or by invoking mutating members. Therefore `ref this T` extensions are allowed as long as `T` is constrained to be a struct.

On the other hand `in` extension methods exist specifically to reduce implicit copying. However any use of an `in T` parameter will have to be done through an interface member. Since all interface members are considered mutating, any such use would require a copy. - Instead of reducing copying, the effect would be the opposite. Therefore `in this T` is not allowed when `T` is a generic type parameter regardless of constraints.

Valid kinds of extension methods (recap):

The following forms of `this` declaration in an extension method are now allowed:

1. `this T arg` - regular byval extension. (existing case)
 - `T` can be any type, including reference types or type parameters. Instance will be the same variable after the call. Allows implicit conversions of *this-argument-conversion* kind. Can be called on RValues.
 - `in this T self` - `in` extension. `T` must be an actual struct type. Instance will be the same variable after the call. Allows implicit conversions of *this-argument-conversion* kind. Can be called on RValues (may be invoked on a temp if needed).

- `ref this T self` - `ref` extension. T must be a struct type or a generic type parameter constrained to be a struct. Instance may be written to by the invocation. Allows only identity conversions. Must be called on writable LValue. (never invoked via a temp).

ReadOnly ref locals.

Motivation.

Once `ref readonly` members were introduced, it was clear from the use that they need to be paired with appropriate kind of local. Evaluation of a member may produce or observe side effects, therefore if the result must be used more than once, it needs to be stored. Ordinary `ref` locals do not help here since they cannot be assigned a `readonly` reference.

Solution.

Allow declaring `ref readonly` locals. This is a new kind of `ref` locals that is not writable. As a result `ref readonly` locals can accept references to readonly variables without exposing these variables to writes.

Declaring and using `ref readonly` locals.

The syntax of such locals uses `ref readonly` modifiers at declaration site (in that specific order). Similarly to ordinary `ref` locals, `ref readonly` locals must be ref-initialized at declaration. Unlike regular `ref` locals, `ref readonly` locals can refer to `readonly` LValues like `in` parameters, `readonly` fields, `ref readonly` methods.

For all purposes a `ref readonly` local is treated as a `readonly` variable. Most of the restrictions on the use are the same as with `readonly` fields or `in` parameters.

For example fields of an `in` parameter which has a struct type are all recursively classified as `readonly` variables .

```
C#
```

```
static readonly ref Vector3 M1() => . . .  
  
static readonly ref Vector3 M1_Trace()  
{  
    // OK
```

```

ref readonly var r1 = ref M1();

// Not valid. Need an LValue
ref readonly Vector3 r2 = ref default(Vector3);

// Not valid. r1 is readonly.
Mutate(ref r1);

// OK.
Print(in r1);

// OK.
return ref r1;
}

```

Restrictions on use of `ref readonly` locals

Except for their `readonly` nature, `ref readonly` locals behave like ordinary `ref` locals and are subject to exactly same restrictions.

For example restrictions related to capturing in closures, declaring in `async` methods or the `safe-to-return` analysis equally applies to `ref readonly` locals.

Ternary `ref` expressions. (aka "Conditional LValues")

Motivation

Use of `ref` and `ref readonly` locals exposed a need to ref-initialize such locals with one or another target variable based on a condition.

A typical workaround is to introduce a method like:

```

C#

ref T Choice(bool condition, ref T consequence, ref T alternative)
{
    if (condition)
    {
        return ref consequence;
    }
    else
    {
        return ref alternative;
    }
}

```

Note that `Choice` is not an exact replacement of a ternary since *all* arguments must be evaluated at the call site, which was leading to unintuitive behavior and bugs.

The following will not work as expected:

```
C#
```

```
// will crash with NRE because 'arr[0]' will be executed unconditionally
ref var r = Choice(arr != null, ref arr[0], ref otherArr[0]);
```

Solution

Allow special kind of conditional expression that evaluates to a reference to one of LValue argument based on a condition.

Using `ref` ternary expression.

The syntax for the `ref` flavor of a conditional expression is `<condition> ? ref <consequence> : ref <alternative>;`

Just like with the ordinary conditional expression only `<consequence>` or `<alternative>` is evaluated depending on result of the boolean condition expression.

Unlike ordinary conditional expression, `ref` conditional expression:

- requires that `<consequence>` and `<alternative>` are LValues.
- `ref` conditional expression itself is an LValue and
- `ref` conditional expression is writeable if both `<consequence>` and `<alternative>` are writeable LValues

Examples:

`ref` ternary is an LValue and as such it can be passed/assigned/returned by reference;

```
C#
```

```
// pass by reference
foo(ref (arr != null ? ref arr[0]: ref otherArr[0]));

// return by reference
return ref (arr != null ? ref arr[0]: ref otherArr[0]);
```

Being an LValue, it can also be assigned to.

```
C#
```

```

// assign to
(arr != null ? ref arr[0]: ref otherArr[0]) = 1;

// error. readOnlyField is readonly and thus conditional expression is
readonly
(arr != null ? ref arr[0]: ref obj.readOnlyField) = 1;

```

Can be used as a receiver of a method call and skip copying if necessary.

C#

```

// no copies
(arr != null ? ref arr[0]: ref otherArr[0]).StructMethod();

// invoked on a copy.
// The receiver is `readonly` because readOnlyField is readonly.
(arr != null ? ref arr[0]: ref obj.readOnlyField).StructMethod();

// no copies. `ReadOnlyStructMethod` is a method on a `readonly` struct
// and can be invoked directly on a readonly receiver
(arr != null ? ref arr[0]: ref
obj.readOnlyField).ReadOnlyStructMethod();

```

`ref` ternary can be used in a regular (not `ref`) context as well.

C#

```

// only an example
// a regular ternary could work here just the same
int x = (arr != null ? ref arr[0]: ref otherArr[0]);

```

Drawbacks

I can see two major arguments against enhanced support for references and readonly references:

1. The problems that are solved here are very old. Why suddenly solve them now, especially since it would not help existing code?

As we find C# and .Net used in new domains, some problems become more prominent. As examples of environments that are more critical than average about computation overheads, I can list

- cloud/datacenter scenarios where computation is billed for and responsiveness is a competitive advantage.
- Games/VR/AR with soft-realtime requirements on latencies

This feature does not sacrifice any of the existing strengths such as type-safety, while allowing to lower overheads in some common scenarios.

2. Can we reasonably guarantee that the callee will play by the rules when it opts into `readonly` contracts?

We have similar trust when using `out`. Incorrect implementation of `out` can cause unspecified behavior, but in reality it rarely happens.

Making the formal verification rules familiar with `ref readonly` would further mitigate the trust issue.

Alternatives

The main competing design is really "do nothing".

Compile time enforcement of safety for ref-like types

Article • 2022-08-09 • 16 minutes to read

Introduction

The main reason for the additional safety rules when dealing with types like `Span<T>` and `ReadOnlySpan<T>` is that such types must be confined to the execution stack.

There are two reasons why `Span<T>` and similar types must be a stack-only types.

1. `Span<T>` is semantically a struct containing a reference and a range - `(ref T data, int length)`. Regardless of actual implementation, writes to such struct would not be atomic. Concurrent "tearing" of such struct would lead to the possibility of `length` not matching the `data`, causing out-of-range accesses and type-safety violations, which ultimately could result in GC heap corruption in seemingly "safe" code.
2. Some implementations of `Span<T>` literally contain a managed pointer in one of its fields. Managed pointers are not supported as fields of heap objects and code that manages to put a managed pointer on the GC heap typically crashes at JIT time.

All the above problems would be alleviated if instances of `Span<T>` are constrained to exist only on the execution stack.

An additional problem arises due to composition. It would be generally desirable to build more complex data types that would embed `Span<T>` and `ReadOnlySpan<T>` instances. Such composite types would have to be structs and would share all the hazards and requirements of `Span<T>`. As a result the safety rules described here should be viewed as applicable to the whole range of *ref-like types*.

The [draft language specification](#) is intended to ensure that values of a ref-like type occur only on the stack.

Generalized ref-like types in source code

`ref-like` structs are explicitly marked in the source code using `ref` modifier:

```
C#
```

```

ref struct TwoSpans<T>
{
    // can have ref-like instance fields
    public Span<T> first;
    public Span<T> second;
}

// error: arrays of ref-like types are not allowed.
TwoSpans<T>[] arr = null;

```

Designating a struct as ref-like will allow the struct to have ref-like instance fields and will also make all the requirements of ref-like types applicable to the struct.

Metadata representation of ref-like structs

Ref-like structs will be marked with `System.Runtime.CompilerServices.IsRefLikeAttribute` attribute.

The attribute will be added to common base libraries such as `mscorlib`. In a case if the attribute is not available, compiler will generate an internal one similarly to other embedded-on-demand attributes such as `IsReadOnlyAttribute`.

An additional measure will be taken to prevent the use of ref-like structs in compilers not familiar with the safety rules (this includes C# compilers prior to the one in which this feature is implemented).

Having no other good alternatives that work in old compilers without servicing, an `Obsolete` attribute with a known string will be added to all ref-like structs. Compilers that know how to use ref-like types will ignore this particular form of `Obsolete`.

A typical metadata representation:

```

C#

[IsRefLike]
[Obsolete("Types with embedded references are not supported in this
version of your compiler.")]
public struct TwoSpans<T>
{
    // . . . .
}

```

NOTE: it is not the goal to make it so that any use of ref-like types on old compilers fails 100%. That is hard to achieve and is not strictly necessary. For example there would

always be a way to get around the `Obsolete` using dynamic code or, for example, creating an array of ref-like types through reflection.

In particular, if user wants to actually put an `Obsolete` or `Deprecated` attribute on a ref-like type, we will have no choice other than not emitting the predefined one since `Obsolete` attribute cannot be applied more than once..

Examples:

C#

```
SpanLikeType M1(ref SpanLikeType x, Span<byte> y)
{
    // this is all valid, unconcerned with stack-referring stuff
    var local = new SpanLikeType(y);
    x = local;
    return x;
}

void Test1(ref SpanLikeType param1, Span<byte> param2)
{
    Span<byte> stackReferring1 = stackalloc byte[10];
    var stackReferring2 = new SpanLikeType(stackReferring1);

    // this is allowed
    stackReferring2 = M1(ref stackReferring2, stackReferring1);

    // this is NOT allowed
    stackReferring2 = M1(ref param1, stackReferring1);

    // this is NOT allowed
    param1 = M1(ref stackReferring2, stackReferring1);

    // this is NOT allowed
    param2 = stackReferring1.Slice(10);

    // this is allowed
    param1 = new SpanLikeType(param2);

    // this is allowed
    stackReferring2 = param1;
}

ref SpanLikeType M2(ref SpanLikeType x)
{
    return ref x;
}

ref SpanLikeType Test2(ref SpanLikeType param1, Span<byte> param2)
{
    Span<byte> stackReferring1 = stackalloc byte[10];
```

```

var stackReferring2 = new SpanLikeType(stackReferring1);

ref var stackReferring3 = M2(ref stackReferring2);

// this is allowed
stackReferring3 = M1(ref stackReferring2, stackReferring1);

// this is allowed
M2(ref stackReferring3) = stackReferring2;

// this is NOT allowed
M1(ref param1) = stackReferring2;

// this is NOT allowed
param1 = stackReferring3;

// this is NOT allowed
return ref stackReferring3;

// this is allowed
return ref param1;
}

```

Draft language specification

Below we describe a set of safety rules for ref-like types (`ref structs`) to ensure that values of these types occur only on the stack. A different, simpler set of safety rules would be possible if locals cannot be passed by reference. This specification would also permit the safe reassignment of ref locals.

Overview

We associate with each expression at compile-time the concept of what scope that expression is permitted to escape to, "safe-to-escape". Similarly, for each lvalue we maintain a concept of what scope a reference to it is permitted to escape to, "ref-safe-to-escape". For a given lvalue expression, these may be different.

These are analogous to the "safe to return" of the ref locals feature, but it is more fine-grained. Where the "safe-to-return" of an expression records only whether (or not) it may escape the enclosing method as a whole, the safe-to-escape records which scope it may escape to (which scope it may not escape beyond). The basic safety mechanism is enforced as follows. Given an assignment from an expression E1 with a safe-to-escape scope S1, to an (lvalue) expression E2 with safe-to-escape scope S2, it is an error if S2 is a wider scope than S1. By construction, the two scopes S1 and S2 are in a nesting

relationship, because a legal expression is always *safe-to-return* from some scope enclosing the expression.

For the time being it is sufficient, for the purpose of the analysis, to support just two scopes - external to the method, and top-level scope of the method. That is because ref-like values with inner scopes cannot be created and ref locals do not support re-assignment. The rules, however, can support more than two scope levels.

The precise rules for computing the *safe-to-return* status of an expression, and the rules governing the legality of expressions, follow.

ref-safe-to-escape

The *ref-safe-to-escape* is a scope, enclosing an lvalue expression, to which it is safe for a ref to the lvalue to escape to. If that scope is the entire method, we say that a ref to the lvalue is *safe to return* from the method.

The *ref-safe-to-escape* scope for an lvalue expression can never be to a greater scope than the *safe-to-escape* for the same value. That means when the spec limits the *safe-to-escape* of a value it is implicitly also limiting the *ref-safe-to-escape* as well. However *ref-safe-to-escape* scope can be to a smaller scope than *safe-to-escape*. Consider that non-ref locals have *safe-to-escape* scope outside method but *ref-safe-to-escape* inside the method.

safe-to-escape

The *safe-to-escape* is a scope, enclosing an expression, to which it is safe for the value to escape to. If that scope is the entire method, we say that the value is *safe to return* from the method.

An expression whose type is not a `ref struct` type is always *safe-to-return* from the entire enclosing method. Otherwise we refer to the rules below.

Parameters

An lvalue designating a formal parameter is *ref-safe-to-escape* (by reference) as follows:

- If the parameter is a `ref`, `out`, or `in` parameter, it is *ref-safe-to-escape* from the entire method (e.g. by a `return ref` statement); otherwise
- If the parameter is the `this` parameter of a struct type, it is *ref-safe-to-escape* to the top-level scope of the method (but not from the entire method itself); [Sample](#)

- Otherwise the parameter is a value parameter, and it is *ref-safe-to-escape* to the top-level scope of the method (but not from the method itself).

An expression that is an rvalue designating the use of a formal parameter is *safe-to-escape* (by value) from the entire method (e.g. by a `return` statement). This applies to the `this` parameter as well.

Locals

An lvalue designating a local variable is *ref-safe-to-escape* (by reference) as follows:

- If the variable is a `ref` variable, then its *ref-safe-to-escape* is taken from the *ref-safe-to-escape* of its initializing expression; otherwise
- The variable is *ref-safe-to-escape* the scope in which it was declared.

An expression that is an rvalue designating the use of a local variable is *safe-to-escape* (by value) as follows:

- But the general rule above, a local whose type is not a `ref struct` type is *safe-to-return* from the entire enclosing method.
- If the variable is an iteration variable of a `foreach` loop, then the variable's *safe-to-escape* scope is the same as the *safe-to-escape* of the `foreach` loop's expression.
- A local of `ref struct` type and uninitialized at the point of declaration is *safe-to-return* from the entire enclosing method.
- Otherwise the variable's type is a `ref struct` type, and the variable's declaration requires an initializer. The variable's *safe-to-escape* scope is the same as the *safe-to-escape* of its initializer.

Field reference

An lvalue designating a reference to a field, `e.F`, is *ref-safe-to-escape* (by reference) as follows:

- If `e` is of a reference type, it is *ref-safe-to-escape* from the entire method; otherwise
- If `e` is of a value type, its *ref-safe-to-escape* is taken from the *ref-safe-to-escape* of `e`.

An rvalue designating a reference to a field, `e.F`, has a *safe-to-escape* scope that is the same as the *safe-to-escape* of `e`.

Operators including `?:`

The application of a user-defined operator is treated as a method invocation.

For an operator that yields an rvalue, such as `e1 + e2` or `c ? e1 : e2`, the *safe-to-escape* of the result is the narrowest scope among the *safe-to-escape* of the operands of the operator. As a consequence, for a unary operator that yields an rvalue, such as `+e`, the *safe-to-escape* of the result is the *safe-to-escape* of the operand.

For an operator that yields an lvalue, such as `c ? ref e1 : ref e2`

- the *ref-safe-to-escape* of the result is the narrowest scope among the *ref-safe-to-escape* of the operands of the operator.
- the *safe-to-escape* of the operands must agree, and that is the *safe-to-escape* of the resulting lvalue.

Method invocation

An lvalue resulting from a ref-returning method invocation `e1.M(e2, ...)` is *ref-safe-to-escape* the smallest of the following scopes:

- The entire enclosing method
- the *ref-safe-to-escape* of all `ref` and `out` argument expressions (excluding the receiver)
- For each `in` parameter of the method, if there is a corresponding expression that is an lvalue, its *ref-safe-to-escape*, otherwise the nearest enclosing scope
- the *safe-to-escape* of all argument expressions (including the receiver)

Note: the last bullet is necessary to handle code such as

```
C#
```

```
var sp = new Span(...)  
return ref sp[0];
```

or

```
C#
```

```
return ref M(sp, 0);
```

An rvalue resulting from a method invocation `e1.M(e2, ...)` is *safe-to-escape* from the smallest of the following scopes:

- The entire enclosing method

- the *safe-to-escape* of all argument expressions (including the receiver)

An Rvalue

An rvalue is *ref-safe-to-escape* from the nearest enclosing scope. This occurs for example in an invocation such as `M(ref d.Length)` where `d` is of type `dynamic`. It is also consistent with (and perhaps subsumes) our handling of arguments corresponding to `in` parameters.

Property invocations

A property invocation (either `get` or `set`) is treated as a method invocation of the underlying method by the above rules.

`stackalloc`

A `stackalloc` expression is an rvalue that is *safe-to-escape* to the top-level scope of the method (but not from the entire method itself).

Constructor invocations

A `new` expression that invokes a constructor obeys the same rules as a method invocation that is considered to return the type being constructed.

In addition *safe-to-escape* is no wider than the smallest of the *safe-to-escape* of all arguments/operands of the object initializer expressions, recursively, if initializer is present.

Span constructor

The language relies on `Span<T>` not having a constructor of the following form:

```
C#  
  
void Example(ref int x)  
{  
    // Create a span of length one  
    var span = new Span<int>(ref x);  
}
```

Such a constructor makes `Span<T>` which are used as fields indistinguishable from a `ref` field. The safety rules described in this document depend on `ref` fields not being a valid construct in C# or .NET.

default expressions

A `default` expression is *safe-to-escape* from the entire enclosing method.

Language Constraints

We wish to ensure that no `ref` local variable, and no variable of `ref struct` type, refers to stack memory or variables that are no longer alive. We therefore have the following language constraints:

- Neither a `ref` parameter, nor a `ref` local, nor a parameter or local of a `ref struct` type can be lifted into a lambda or local function.
- Neither a `ref` parameter nor a parameter of a `ref struct` type may be an argument on an iterator method or an `async` method.
- Neither a `ref` local, nor a local of a `ref struct` type may be in scope at the point of a `yield return` statement or an `await` expression.
- A `ref struct` type may not be used as a type argument, or as an element type in a tuple type.
- A `ref struct` type may not be the declared type of a field, except that it may be the declared type of an instance field of another `ref struct`.
- A `ref struct` type may not be the element type of an array.
- A value of a `ref struct` type may not be boxed:
 - There is no conversion from a `ref struct` type to the type `object` or the type `System.ValueType`.
 - A `ref struct` type may not be declared to implement any interface
 - No instance method declared in `object` or in `System.ValueType` but not overridden in a `ref struct` type may be called with a receiver of that `ref struct` type.
 - No instance method of a `ref struct` type may be captured by method conversion to a delegate type.

- For a ref reassignment `e1 = ref e2`, the *ref-safe-to-escape* of `e2` must be at least as wide a scope as the *ref-safe-to-escape* of `e1`.
- For a ref return statement `return ref e1`, the *ref-safe-to-escape* of `e1` must be *ref-safe-to-escape* from the entire method. (TODO: Do we also need a rule that `e1` must be *safe-to-escape* from the entire method, or is that redundant?)
- For a return statement `return e1`, the *safe-to-escape* of `e1` must be *safe-to-escape* from the entire method.
- For an assignment `e1 = e2`, if the type of `e1` is a `ref struct` type, then the *safe-to-escape* of `e2` must be at least as wide a scope as the *safe-to-escape* of `e1`.
- For a method invocation if there is a `ref` or `out` argument of a `ref struct` type (including the receiver unless the type is `readonly`), with *safe-to-escape* E1, then no argument (including the receiver) may have a narrower *safe-to-escape* than E1.

Sample

- A local function or anonymous function may not refer to a local or parameter of `ref struct` type declared in an enclosing scope.

Open Issue: We need some rule that permits us to produce an error when needing to spill a stack value of a `ref struct` type at an `await` expression, for example in the code

C#

```
Foo(new Span<int>(…), await e2);
```

Explanations

These explanations and samples help explain why many of the safety rules above exist

Method Arguments Must Match

When invoking a method where there is an `out` or `ref` parameter that is a `ref struct` then all of the `ref struct` parameters need to have the same lifetime. This is necessary because C# must make all of its decisions around lifetime safety based on the information available in the signature of the method and the lifetime of the values at the call site.

When there are `ref` parameters that are `ref struct` then there is the potential that they could swap around their contents. Hence at the call site we must ensure all of these **potential** swaps are compatible. If the language didn't enforce that then it will allow for bad code like the following.

```
C#  
  
void M1(ref Span<int> s1)  
{  
    Span<int> s2 = stackalloc int[1];  
    Swap(ref s1, ref s2);  
}  
  
void Swap(ref Span<int> x, ref Span<int> y)  
{  
    // This will effectively assign the stackalloc to the s1 parameter and  
    // allow it  
    // to escape to the caller of M1  
    ref x = ref y;  
}
```

This analysis of `ref` parameters includes the receiver in instance methods. This is necessary because it can be used to store values passed in as parameters, just as a `ref` parameter could. This means with mismatched lifetimes you could create a type safety hole in the following way:

```
C#  
  
ref struct S  
{  
    public Span<int> Span;  
  
    public void Set(Span<int> span)  
    {  
        Span = span;  
    }  
}  
  
void Broken(ref S s)  
{  
    Span<int> span = stackalloc int[1];  
  
    // The result of a stackalloc is now stored in s.Span and escaped to the  
    // caller  
    // of Broken  
    s.Set(span);  
}
```

For the purpose of this analysis the receiver is considered an `in`, not a `ref`, if the type is a `readonly struct`. In that case the receiver cannot be used to store values from other parameters, it is effectively an `in` parameter for analysis purposes. Hence the same example above is legal when `S` is `readonly` because the `span` cannot be stored anywhere.

Struct This Escape

When it comes to span safety rules, the `this` value in an instance member is modeled as a parameter to the member. Now for a `struct` the type of `this` is actually `ref S` where in a `class` it's simply `S` (for members of a `class / struct` named `S`).

Yet `this` has different escaping rules than other `ref` parameters. Specifically it is not ref-safe-to-escape while other parameters are:

```
C#  
  
ref struct S  
{  
    int Field;  
  
    // Illegal because `this` isn't safe to escape as ref  
    ref int Get() => ref Field;  
  
    // Legal  
    ref int GetParam(ref int p) => ref p;  
}
```

The reason for this restriction actually has little to do with `struct` member invocation. There are some rules that need to be worked out with respect to member invocation on `struct` members where the receiver is an rvalue. But that is very approachable.

The reason for this restriction is actually about interface invocation. Specifically it comes down to whether or not the following sample should or should not compile;

```
C#  
  
interface I1  
{  
    ref int Get();  
}  
  
ref int Use<T>(T p)  
    where T : I1  
{
```

```
    return ref p.Get();  
}
```

Consider the case where `T` is instantiated as a `struct`. If the `this` parameter is ref-safe-to-escape then the return of `p.Get` could point to the stack (specifically it could be a field inside of the instantiated type of `T`). That means the language could not allow this sample to compile as it could be returning a `ref` to a stack location. On the other hand if `this` is not ref-safe-to-escape then `p.Get` cannot refer to the stack and hence it's safe to return.

This is why the escapability of `this` in a `struct` is really all about interfaces. It can absolutely be made to work but it has a trade off. The design eventually came down in favor of making interfaces more flexible.

There is potential for us to relax this in the future though.

Future Considerations

Length one `Span<T>` over ref values

Though not legal today there are cases where creating a length one `Span<T>` instance over a value would be beneficial:

```
C#  
  
void RefExample()  
{  
    int x = ...;  
  
    // Today creating a length one Span<int> requires a stackalloc and a new  
    // local  
    Span<int> span1 = stackalloc [] { x };  
    Use(span1);  
    x = span1[0];  
  
    // Simpler to just allow length one span  
    var span2 = new Span<int>(ref x);  
    Use(span2);  
}
```

This feature gets more compelling if we lift the restrictions on [fixed sized buffers](#) as it would allow for `Span<T>` instances of even greater length.

If there is ever a need to go down this path then the language could accommodate this by ensuring such `Span<T>` instances were downward facing only. That is they were only ever *safe-to-escape* to the scope in which they were created. This ensure the language never had to consider a `ref` value escaping a method via a `ref struct` return or field of `ref struct`. This would likely also require further changes to recognize such constructors as capturing a `ref` parameter in this way though.

Conditional ref expressions

Article • 2021-09-21 • 2 minutes to read

The pattern of binding a ref variable to one or another expression conditionally is not currently expressible in C#.

The typical workaround is to introduce a method like:

```
C#  
  
ref T Choice(bool condition, ref T consequence, ref T alternative)  
{  
    if (condition)  
    {  
        return ref consequence;  
    }  
    else  
    {  
        return ref alternative;  
    }  
}
```

Note that this is not an exact replacement of a ternary since all arguments must be evaluated at the call site.

The following will not work as expected:

```
C#  
  
// will crash with NRE because 'arr[0]' will be executed  
unconditionally  
ref var r = ref Choice(arr != null, ref arr[0], ref otherArr[0]);
```

The proposed syntax would look like:

```
C#  
  
<condition> ? ref <consequence> : ref <alternative>;
```

The above attempt with "Choice" can be *correctly* written using ref ternary as:

```
C#  
  
ref var r = ref (arr != null ? ref arr[0]: ref otherArr[0]);
```

The difference from Choice is that consequence and alternative expressions are accessed in a *truly* conditional manner, so we do not see a crash if `arr == null`

The ternary ref is just a ternary where both alternative and consequence are refs. It will naturally require that consequence/alternative operands are LValues. It will also require that consequence and alternative have types that are identity convertible to each other.

The type of the expression will be computed similarly to the one for the regular ternary. I.E. in a case if consequence and alternative have identity convertible, but different types, the existing type-merging rules will apply.

Safe-to-return will be assumed conservatively from the conditional operands. If either is unsafe to return the whole thing is unsafe to return.

Ref ternary is an LValue and as such it can be passed/assigned/returned by reference;

C#

```
// pass by reference
foo(ref (arr != null ? ref arr[0]: ref otherArr[0]));

// return by reference
return ref (arr != null ? ref arr[0]: ref otherArr[0]);
```

Being an LValue, it can also be assigned to.

C#

```
// assign to
(arr != null ? ref arr[0]: ref otherArr[0]) = 1;
```

Ref ternary can be used in a regular (not ref) context as well. Although it would not be common since you could as well just use a regular ternary.

C#

```
int x = (arr != null ? ref arr[0]: ref otherArr[0]);
```

Implementation notes:

The complexity of the implementation would seem to be the size of a moderate-to-large bug fix. - I.E not very expensive. I do not think we need any changes to the syntax or parsing. There is no effect on metadata or interop. The feature is completely expression based. No effect on debugging/PDB either

Unmanaged type constraint

Article • 2021-09-21 • 4 minutes to read

Summary

The unmanaged constraint feature will give language enforcement to the class of types known as "unmanaged types" in the C# language spec. This is defined in section 18.2 as a type which is not a reference type and doesn't contain reference type fields at any level of nesting.

Motivation

The primary motivation is to make it easier to author low level interop code in C#. Unmanaged types are one of the core building blocks for interop code, yet the lack of support in generics makes it impossible to create re-usable routines across all unmanaged types. Instead developers are forced to author the same boiler plate code for every unmanaged type in their library:

C#

```
int Hash(Point point) { ... }  
int Hash(TimeSpan timeSpan) { ... }
```

To enable this type of scenario the language will be introducing a new constraint: unmanaged:

C#

```
void Hash<T>(T value) where T : unmanaged  
{  
    ...  
}
```

This constraint can only be met by types which fit into the unmanaged type definition in the C# language spec. Another way of looking at it is that a type satisfies the unmanaged constraint if it can also be used as a pointer.

C#

```
Hash(new Point()); // Okay  
Hash(42); // Okay
```

```
Hash("hello") // Error: Type string does not satisfy the unmanaged
constraint
```

Type parameters with the unmanaged constraint can use all the features available to unmanaged types: pointers, fixed, etc ...

```
C#

void Hash<T>(T value) where T : unmanaged
{
    // Okay
    fixed (T* p = &value)
    {
        ...
    }
}
```

This constraint will also make it possible to have efficient conversions between structured data and streams of bytes. This is an operation that is common in networking stacks and serialization layers:

```
C#

Span<byte> Convert<T>(ref T value) where T : unmanaged
{
    ...
}
```

Such routines are advantageous because they are provably safe at compile time and allocation free. Interop authors today can not do this (even though it's at a layer where perf is critical). Instead they need to rely on allocating routines that have expensive runtime checks to verify values are correctly unmanaged.

Detailed design

The language will introduce a new constraint named `unmanaged`. In order to satisfy this constraint a type must be a struct and all the fields of the type must fall into one of the following categories:

- Have the type `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `IntPtr` or `UIntPtr`.
- Be any `enum` type.
- Be a pointer type.
- Be a user defined struct that satisfies the `unmanaged` constraint.

Compiler generated instance fields, such as those backing auto-implemented properties, must also meet these constraints.

For example:

```
C#  
  
// Unmanaged type  
struct Point  
{  
    int X;  
    int Y {get; set;}  
}  
  
// Not an unmanaged type  
struct Student  
{  
    string FirstName;  
    string LastName;  
}
```

The `unmanaged` constraint cannot be combined with `struct`, `class` or `new()`. This restriction derives from the fact that `unmanaged` implies `struct` hence the other constraints do not make sense.

The `unmanaged` constraint is not enforced by CLR, only by the language. To prevent misuse by other languages, methods which have this constraint will be protected by a `mod-req`. This will prevent other languages from using type arguments which are not unmanaged types.

The token `unmanaged` in the constraint is not a keyword, nor a contextual keyword. Instead it is like `var` in that it is evaluated at that location and will either:

- Bind to user defined or referenced type named `unmanaged`: This will be treated just as any other named type constraint is treated.
- Bind to no type: This will be interpreted as the `unmanaged` constraint.

In the case there is a type named `unmanaged` and it is available without qualification in the current context, then there will be no way to use the `unmanaged` constraint. This parallels the rules surrounding the feature `var` and user defined types of the same name.

Drawbacks

The primary drawback of this feature is that it serves a small number of developers: typically low level library authors or frameworks. Hence it's spending precious language time for a small number of developers.

Yet these frameworks are often the basis for the majority of .NET applications out there. Hence performance / correctness wins at this level can have a ripple effect on the .NET ecosystem. This makes the feature worth considering even with the limited audience.

Alternatives

There are a couple of alternatives to consider:

- The status quo: The feature is not justified on its own merits and developers continue to use the implicit opt in behavior.

Questions

Metadata Representation

The F# language encodes the constraint in the signature file which means C# cannot re-use their representation. A new attribute will need to be chosen for this constraint. Additionally a method which has this constraint must be protected by a mod-req.

Blittable vs. Unmanaged

The F# language has a very [similar feature](#) which uses the keyword unmanaged. The blittable name comes from the use in Midori. May want to look to precedence here and use unmanaged instead.

Resolution The language decide to use unmanaged

Verifier

Does the verifier / runtime need to be updated to understand the use of pointers to generic type parameters? Or can it simply work as is without changes?

Resolution No changes needed. All pointer types are simply unverifiable.

Design meetings

n/a

Indexing `fixed` fields should not require pinning regardless of the movable/unmovable context.

Article • 2021-09-21 • 2 minutes to read

The change has the size of a bug fix. It can be in 7.3 and does not conflict with whatever direction we take further. This change is only about allowing the following scenario to work even though `s` is moveable. It is already valid when `s` is not moveable.

NOTE: in either case, it still requires `unsafe` context. It is possible to read uninitialized data or even out of range. That is not changing.

C#

```
unsafe struct S
{
    public fixed int myFixedField[10];
}

class Program
{
    static S s;

    unsafe static void Main()
    {
        int p = s.myFixedField[5]; // indexing fixed-size array fields would
        be ok
    }
}
```

The main “challenge” that I see here is how to explain the relaxation in the spec. In particular, since the following would still need pinning. (because `s` is moveable and we explicitly use the field as a pointer)

C#

```
unsafe struct S
{
    public fixed int myFixedField[10];
}

class Program
{
    static S s;
```

```
unsafe static void Main()
{
    int* ptr = s.myFixedField; // taking a pointer explicitly still
    requires pinning.
    int p = ptr[5];
}
}
```

One reason why we require pinning of the target when it is movable is the artifact of our code generation strategy, - we always convert to an unmanaged pointer and thus force the user to pin via `fixed` statement. However, conversion to unmanaged is unnecessary when doing indexing. The same unsafe pointer math is equally applicable when we have the receiver in the form of a managed pointer. If we do that, then the intermediate ref is managed (GC-tracked) and the pinning is unnecessary.

The change <https://github.com/dotnet/roslyn/pull/24966> is a prototype PR that relaxes this requirement.

Pattern-based `fixed` statement

Article • 2021-09-21 • 3 minutes to read

Summary

Introduce a pattern that would allow types to participate in `fixed` statements.

Motivation

The language provides a mechanism for pinning managed data and obtain a native pointer to the underlying buffer.

```
C#
```

```
fixed(byte* ptr = byteArray)
{
    // ptr is a native pointer to the first element of the array
    // byteArray is protected from being moved/collected by the GC for the
    duration of this block
}
```

The set of types that can participate in `fixed` is hardcoded and limited to arrays and `System.String`. Hardcoding "special" types does not scale when new primitives such as `ImmutableArray<T>`, `Span<T>`, `Utf8String` are introduced.

In addition, the current solution for `System.String` relies on a fairly rigid API. The shape of the API implies that `System.String` is a contiguous object that embeds UTF16 encoded data at a fixed offset from the object header. Such approach has been found problematic in several proposals that could require changes to the underlying layout. It would be desirable to be able to switch to something more flexible that decouples `System.String` object from its internal representation for the purpose of unmanaged interop.

Detailed design

Pattern

A viable pattern-based "fixed" need to:

- Provide the managed references to pin the instance and to initialize the pointer (preferably this is the same reference)
- Convey unambiguously the type of the unmanaged element (i.e. "char" for "string")
- Prescribe the behavior in "empty" case when there is nothing to refer to.
- Should not push API authors toward design decisions that hurt the use of the type outside of `fixed`.

I think the above could be satisfied by recognizing a specially named ref-returning member: `ref [readonly] T GetPinnableReference()`.

In order to be used by the `fixed` statement the following conditions must be met:

1. There is only one such member provided for a type.
2. Returns by `ref` or `ref readonly`. (`readonly` is permitted so that authors of immutable/readonly types could implement the pattern without adding writeable API that could be used in safe code)
3. T is an unmanaged type. (since `T*` becomes the pointer type. The restriction will naturally expand if/when the notion of "unmanaged" is expanded)
4. Returns managed `nullptr` when there is no data to pin – probably the cheapest way to convey emptiness. (note that "" string returns a ref to '\0' since strings are null-terminated)

Alternatively for the #3 we can allow the result in empty cases be undefined or implementation-specific. That, however, may make the API more dangerous and prone to abuse and unintended compatibility burdens.

Translation

C#

```
fixed(byte* ptr = thing)
{
    // <BODY>
}
```

becomes the following pseudocode (not all expressible in C#)

C#

```
byte* ptr;
// specially decorated "pinned" IL local slot, not visible to user code.
pinned ref byte _pinned;

try
```

```

{
    // NOTE: null check is omitted for value types
    // NOTE: `thing` is evaluated only once (temporary is introduced if
    necessary)
    if (thing != null)
    {
        // obtain and "pin" the reference
        _pinned = ref thing.GetPinnableReference();

        // unsafe cast in IL
        ptr = (byte*)_pinned;
    }
    else
    {
        ptr = default(byte*);
    }

    // <BODY>
}
finally // finally can be omitted when not observable
{
    // "unpin" the object
    _pinned = nullptr;
}
}

```

Drawbacks

- GetPinnableReference is intended to be used only in `fixed`, but nothing prevents its use in safe code, so implementor must keep that in mind.

Alternatives

Users can introduce GetPinnableReference or similar member and use it as

```

C#
fixed(byte* ptr = thing.GetPinnableReference())
{
    // <BODY>
}

```

There is no solution for `System.String` if alternative solution is desired.

Unresolved questions

- [] Behavior in "empty" state. - `nullptr` or `undefined` ?

- Should the extension methods be considered ?
- If a pattern is detected on `System.String`, should it win over ?

Ref Local Reassignment

Article • 2021-09-21 • 2 minutes to read

In C# 7.3, we add support for rebinding the referent of a ref local variable or a ref parameter.

We add the following to the set of `assignment_operators`.

```
antlr
assignment_operator
: '=' 'ref'
;
```

The `=ref` operator is called the *ref assignment operator*. It is not a *compound assignment operator*. The left operand must be an expression that binds to a ref local variable, a ref parameter (other than `this`), or an out parameter. The right operand must be an expression that yields an lvalue designating a value of the same type as the left operand.

The right operand must be definitely assigned at the point of the ref assignment.

When the left operand binds to an `out` parameter, it is an error if that `out` parameter has not been definitely assigned at the beginning of the ref assignment operator.

If the left operand is a writable ref (i.e. it designates anything other than a `ref readonly` local or `in` parameter), then the right operand must be a writable lvalue.

The ref assignment operator yields an lvalue of the assigned type. It is writable if the left operand is writable (i.e. not `ref readonly` or `in`).

The safety rules for this operator are:

- For a ref reassignment `e1 = ref e2`, the *ref-safe-to-escape* of `e2` must be at least as wide a scope as the *ref-safe-to-escape* of `e1`.

Where *ref-safe-to-escape* is defined in [Safety for ref-like types](#)

Stackalloc array initializers

Article • 2021-09-21 • 2 minutes to read

Summary

Allow array initializer syntax to be used with `stackalloc`.

Motivation

Ordinary arrays can have their elements initialized at creation time. It seems reasonable to allow that in `stackalloc` case.

The question of why such syntax is not allowed with `stackalloc` arises fairly frequently. See, for example, [#1112](#) ↗

Detailed design

Ordinary arrays can be created through the following syntax:

C#

```
new int[3]
new int[3] { 1, 2, 3 }
new int[] { 1, 2, 3 }
new[] { 1, 2, 3 }
```

We should allow stack allocated arrays be created through:

C#

```
stackalloc int[3]           // currently allowed
stackalloc int[3] { 1, 2, 3 }
stackalloc int[] { 1, 2, 3 }
stackalloc[] { 1, 2, 3 }
```

The semantics of all cases is roughly the same as with arrays.

For example: in the last case the element type is inferred from the initializer and must be an "unmanaged" type.

NOTE: the feature is not dependent on the target being a `Span<T>`. It is just as applicable in `T*` case, so it does not seem reasonable to predicate it on `Span<T>` case.

Translation

The naive implementation could just initialize the array right after creation through a series of element-wise assignments.

Similarly to the case with arrays, it might be possible and desirable to detect cases where all or most of the elements are blittable types and use more efficient techniques by copying over the pre-created state of all the constant elements.

Drawbacks

Alternatives

This is a convenience feature. It is possible to just do nothing.

Expression variables in initializers

Article • 2021-09-21 • 2 minutes to read

Summary

We extend the features introduced in C# 7 to permit expressions containing expression variables (out variable declarations and declaration patterns) in field initializers, property initializers, ctor-initializers, and query clauses.

Motivation

This completes a couple of the rough edges left in the C# language due to lack of time.

Detailed design

We remove the restriction preventing the declaration of expression variables (out variable declarations and declaration patterns) in a ctor-initializer. Such a declared variable is in scope throughout the body of the constructor.

We remove the restriction preventing the declaration of expression variables (out variable declarations and declaration patterns) in a field or property initializer. Such a declared variable is in scope throughout the initializing expression.

We remove the restriction preventing the declaration of expression variables (out variable declarations and declaration patterns) in a query expression clause that is translated into the body of a lambda. Such a declared variable is in scope throughout that expression of the query clause.

Drawbacks

None.

Alternatives

The appropriate scope for expression variables declared in these contexts is not obvious, and deserves further LDM discussion.

Unresolved questions

- What is the appropriate scope for these variables?

Design meetings

None.

Support for == and != on tuple types

Article • 2022-02-23 • 4 minutes to read

Allow expressions `t1 == t2` where `t1` and `t2` are tuple or nullable tuple types of same cardinality, and evaluate them roughly as `temp1.Item1 == temp2.Item1 && temp1.Item2 == temp2.Item2` (assuming `var temp1 = t1; var temp2 = t2;`).

Conversely it would allow `t1 != t2` and evaluate it as `temp1.Item1 != temp2.Item1 || temp1.Item2 != temp2.Item2`.

In the nullable case, additional checks for `temp1.HasValue` and `temp2.HasValue` are used. For instance, `nullableT1 == nullableT2` evaluates as `temp1.HasValue == temp2.HasValue ? (temp1.HasValue ? ... : true) : false`.

When an element-wise comparison returns a non-bool result (for instance, when a non-bool user-defined `operator ==` or `operator !=` is used, or in a dynamic comparison), then that result will be either converted to `bool` or run through `operator true` or `operator false` to get a `bool`. The tuple comparison always ends up returning a `bool`.

As of C# 7.2, such code produces an error (`error CS0019: Operator '==' cannot be applied to operands of type '(...)' and '(...)'`), unless there is a user-defined `operator==`.

Details

When binding the `==` (or `!=`) operator, the existing rules are: (1) dynamic case, (2) overload resolution, and (3) fail. This proposal adds a tuple case between (1) and (2): if both operands of a comparison operator are tuples (have tuple types or are tuple literals) and have matching cardinality, then the comparison is performed element-wise. This tuple equality is also lifted onto nullable tuples.

Both operands (and, in the case of tuple literals, their elements) are evaluated in order from left to right. Each pair of elements is then used as operands to bind the operator `==` (or `!=`), recursively. Any elements with compile-time type `dynamic` cause an error. The results of those element-wise comparisons are used as operands in a chain of conditional AND (or OR) operators.

For instance, in the context of `(int, (int, int)) t1, t2; t1 == (1, (2, 3))` would evaluate as `temp1.Item1 == temp2.Item1 && temp1.Item2.Item1 == temp2.Item2.Item1 && temp1.Item2.Item2 == temp2.Item2.Item2`.

When a tuple literal is used as operand (on either side), it receives a converted tuple type formed by the element-wise conversions which are introduced when binding the operator `==` (or `!=`) element-wise.

For instance, in `(1L, 2, "hello") == (1, 2L, null)`, the converted type for both tuple literals is `(long, long, string)` and the second literal has no natural type.

Deconstruction and conversions to tuple

In `(a, b) == x`, the fact that `x` can deconstruct into two elements does not play a role. That could conceivably be in a future proposal, although it would raise questions about `x == y` (is this a simple comparison or an element-wise comparison, and if so using what cardinality?). Similarly, conversions to tuple play no role.

Tuple element names

When converting a tuple literal, we warn when an explicit tuple element name was provided in the literal, but it doesn't match the target tuple element name. We use the same rule in tuple comparison, so that assuming `(int a, int b) t` we warn on `d` in `t == (c, d: 0)`.

Non-bool element-wise comparison results

If an element-wise comparison is dynamic in a tuple equality, we use a dynamic invocation of the operator `false` and negate that to get a `bool` and continue with further element-wise comparisons.

If an element-wise comparison returns some other non-bool type in a tuple equality, there are two cases:

- if the non-bool type converts to `bool`, we apply that conversion,
- if there is no such conversion, but the type has an operator `false`, we'll use that and negate the result.

In a tuple inequality, the same rules apply except that we'll use the operator `true` (without negation) instead of the operator `false`.

Those rules are similar to the rules involved for using a non-bool type in an `if` statement and some other existing contexts.

Evaluation order and special cases

The left-hand-side value is evaluated first, then the right-hand-side value, then the element-wise comparisons from left to right (including conversions, and with early exit based on existing rules for conditional AND/OR operators).

For instance, if there is a conversion from type `A` to type `B` and a method `(A, A) GetTuple()`, evaluating `(new A(1), (new B(2), new B(3))) == (new B(4), GetTuple())` means:

- `new A(1)`
- `new B(2)`
- `new B(3)`
- `new B(4)`
- `GetTuple()`
- then the element-wise conversions and comparisons and conditional logic is evaluated (convert `new A(1)` to type `B`, then compare it with `new B(4)`, and so on).

Comparing `null` to `null`

This is a special case from regular comparisons, that carries over to tuple comparisons. The `null == null` comparison is allowed, and the `null` literals do not get any type. In tuple equality, this means, `(0, null) == (0, null)` is also allowed and the `null` and tuple literals don't get a type either.

Comparing a nullable struct to `null` without `operator==`

This is another special case from regular comparisons, that carries over to tuple comparisons. If you have a `struct S` without `operator==`, the `(S?)x == null` comparison is allowed, and it is interpreted as `((S?).x).HasValue`. In tuple equality, the same rule is applied, so `(0, (S?)x) == (0, null)` is allowed.

Compatibility

If someone wrote their own `ValueTuple` types with an implementation of the comparison operator, it would have previously been picked up by overload resolution. But since the new tuple case comes before overload resolution, we would handle this case with tuple comparison instead of relying on the user-defined comparison.

Nullable reference types in C#

Article • 2021-09-21 • 7 minutes to read

The goal of this feature is to:

- Allow developers to express whether a variable, parameter or result of a reference type is intended to be null or not.
- Provide warnings when such variables, parameters and results are not used according to that intent.

Expression of intent

The language already contains the `T?` syntax for value types. It is straightforward to extend this syntax to reference types.

It is assumed that the intent of an unadorned reference type `T` is for it to be non-null.

Checking of nullable references

A flow analysis tracks nullable reference variables. Where the analysis deems that they would not be null (e.g. after a check or an assignment), their value will be considered a non-null reference.

A nullable reference can also explicitly be treated as non-null with the postfix `x!` operator (the "damnit" operator), for when flow analysis cannot establish a non-null situation that the developer knows is there.

Otherwise, a warning is given if a nullable reference is dereferenced, or is converted to a non-null type.

A warning is given when converting from `S[]` to `T?[]` and from `S?[]` to `T[]`.

A warning is given when converting from `C<S>` to `C<T?>` except when the type parameter is covariant (`out`), and when converting from `C<S?>` to `C<T>` except when the type parameter is contravariant (`in`).

A warning is given on `C<T?>` if the type parameter has non-null constraints.

Checking of non-null references

A warning is given if a null literal is assigned to a non-null variable or passed as a non-null parameter.

A warning is also given if a constructor does not explicitly initialize non-null reference fields.

We cannot adequately track that all elements of an array of non-null references are initialized. However, we could issue a warning if no element of a newly created array is assigned to before the array is read from or passed on. That might handle the common case without being too noisy.

We need to decide whether `default(T)` generates a warning, or is simply treated as being of the type `T?`.

Metadata representation

Nullability adornments should be represented in metadata as attributes. This means that downlevel compilers will ignore them.

We need to decide if only nullable annotations are included, or there's also some indication of whether non-null was "on" in the assembly.

Generics

If a type parameter `T` has non-nullable constraints, it is treated as non-nullable within its scope.

If a type parameter is unconstrained or has only nullable constraints, the situation is a little more complex: this means that the corresponding type argument could be *either* nullable or non-nullable. The safe thing to do in that situation is to treat the type parameter as *both* nullable and non-nullable, giving warnings when either is violated.

It is worth considering whether explicit nullable reference constraints should be allowed. Note, however, that we cannot avoid having nullable reference types *implicitly* be constraints in certain cases (inherited constraints).

The `class` constraint is non-null. We can consider whether `class?` should be a valid nullable constraint denoting "nullable reference type".

Type inference

In type inference, if a contributing type is a nullable reference type, the resulting type should be nullable. In other words, nullness is propagated.

We should consider whether the `null` literal as a participating expression should contribute nullness. It doesn't today: for value types it leads to an error, whereas for reference types the null successfully converts to the plain type.

C#

```
string? n = "world";
var x = b ? "Hello" : n; // string?
var y = b ? "Hello" : null; // string? or error
var z = b ? 7 : null; // Error today, could be int?
```

Null guard guidance

As a feature, nullable reference types allow developers to express their intent, and provide warnings through flow analysis if that intent is contradicted. There is a common question as to whether or not null guards are necessary.

Example of null guard

C#

```
public void DoWork(Worker worker)
{
    // Guard against worker being null
    if (worker is null)
    {
        throw new ArgumentNullException(nameof(worker));
    }

    // Otherwise use worker argument
}
```

In the previous example, the `DoWork` function accepts a `Worker` and guards against it potentially being `null`. If the `worker` argument is `null`, the `DoWork` function will `throw`. With nullable reference types, the code in the previous example makes the intent that the `Worker` parameter would *not* be `null`. If the `DoWork` function was a public API, such as a NuGet package or a shared library - as guidance you should leave null guards in place. As a public API, the only guarantee that a caller isn't passing `null` is to guard against it.

Express intent

A more compelling use of the previous example is to express that the `Worker` parameter could be `null`, thus making the null guard more appropriate. If you remove the null guard in the following example, the compiler warns that you may be dereferencing null. Regardless, both null guards are still valid.

C#

```
public void DoWork(Worker? worker)
{
    // Guard against worker being null
    if (worker is null)
    {
        throw new ArgumentNullException(nameof(worker));
    }

    // Otherwise use worker argument
}
```

For non-public APIs, such as source code entirely in control by a developer or dev team - the nullable reference types could allow for the safe removal of null guards where the developers can guarantee it is not necessary. The feature can help with warnings, but it cannot guarantee that at runtime code execution could result in a `NullReferenceException`.

Breaking changes

Non-null warnings are an obvious breaking change on existing code, and should be accompanied with an opt-in mechanism.

Less obviously, warnings from nullable types (as described above) are a breaking change on existing code in certain scenarios where the nullability is implicit:

- Unconstrained type parameters will be treated as implicitly nullable, so assigning them to `object` or accessing e.g. `ToString` will yield warnings.
- if type inference infers nullness from `null` expressions, then existing code will sometimes yield nullable rather than non-nullable types, which can lead to new warnings.

So nullable warnings also need to be optional

Finally, adding annotations to an existing API will be a breaking change to users who have opted in to warnings, when they upgrade the library. This, too, merits the ability to

opt in or out. "I want the bug fixes, but I am not ready to deal with their new annotations"

In summary, you need to be able to opt in/out of:

- Nullable warnings
- Non-null warnings
- Warnings from annotations in other files

The granularity of the opt-in suggests an analyzer-like model, where swaths of code can opt in and out with pragmas and severity levels can be chosen by the user. Additionally, per-library options ("ignore the annotations from JSON.NET until I'm ready to deal with the fall out") may be expressible in code as attributes.

The design of the opt-in/transition experience is crucial to the success and usefulness of this feature. We need to make sure that:

- Users can adopt nullability checking gradually as they want to
- Library authors can add nullability annotations without fear of breaking customers
- Despite these, there is not a sense of "configuration nightmare"

Tweaks

We could consider not using the `?` annotations on locals, but just observing whether they are used in accordance with what gets assigned to them. I don't favor this; I think we should uniformly let people express their intent.

We could consider a shorthand `T! x` on parameters, that auto-generates a runtime null check.

Certain patterns on generic types, such as `FirstOrDefault` or `TryGet`, have slightly weird behavior with non-nullable type arguments, because they explicitly yield default values in certain situations. We could try to nuance the type system to accommodate these better. For instance, we could allow `?` on unconstrained type parameters, even though the type argument could already be nullable. I doubt that it is worth it, and it leads to weirdness related to interaction with nullable *value* types.

Nullable value types

We could consider adopting some of the above semantics for nullable value types as well.

We already mentioned type inference, where we could infer `int?` from `(7, null)`, instead of just giving an error.

Another opportunity is to apply the flow analysis to nullable value types. When they are deemed non-null, we could actually allow using as the non-nullable type in certain ways (e.g. member access). We just have to be careful that the things that you can *already* do on a nullable value type will be preferred, for back compat reasons.

Recursive Pattern Matching

Article • 2022-03-24 • 12 minutes to read

Summary

Pattern matching extensions for C# enable many of the benefits of algebraic data types and pattern matching from functional languages, but in a way that smoothly integrates with the feel of the underlying language. Elements of this approach are inspired by related features in the programming languages [F#](#) and [Scala](#).

Detailed design

Is Expression

The `is` operator is extended to test an expression against a *pattern*.

```
antlr
```

```
relational_expression
    : is_pattern_expression
    ;
is_pattern_expression
    : relational_expression 'is' pattern
    ;
```

This form of *relational_expression* is in addition to the existing forms in the C# specification. It is a compile-time error if the *relational_expression* to the left of the `is` token does not designate a value or does not have a type.

Every *identifier* of the pattern introduces a new local variable that is *definitely assigned* after the `is` operator is `true` (i.e. *definitely assigned when true*).

Note: There is technically an ambiguity between *type* in an `is-expression` and *constant_pattern*, either of which might be a valid parse of a qualified identifier. We try to bind it as a type for compatibility with previous versions of the language; only if that fails do we resolve it as we do an expression in other contexts, to the first thing found (which must be either a constant or a type). This ambiguity is only present on the right-hand-side of an `is` expression.

Patterns

Patterns are used in the *is_pattern* operator, in a *switch_statement*, and in a *switch_expression* to express the shape of data against which incoming data (which we call the input value) is to be compared. Patterns may be recursive so that parts of the data may be matched against sub-patterns.

```
antlr
```

```
pattern
  : declaration_pattern
  | constant_pattern
  | var_pattern
  | positional_pattern
  | property_pattern
  | discard_pattern
  ;
declaration_pattern
  : type simple_designation
  ;
constant_pattern
  : constant_expression
  ;
var_pattern
  : 'var' designation
  ;
positional_pattern
  : type? '(' subpatterns? ')' property_subpattern? simple_designation?
  ;
subpatterns
  : subpattern
  | subpattern ',' subpatterns
  ;
subpattern
  : pattern
  | identifier ':' pattern
  ;
property_subpattern
  : '{' '}'
  | '{' subpatterns ','? '}'
  ;
property_pattern
  : type? property_subpattern simple_designation?
  ;
simple_designation
  : single_variable_designation
  | discard_designation
  ;
discard_pattern
  : '_'
  ;
```

Declaration Pattern

```
antlr
```

```
declaration_pattern
    : type simple_designation
    ;
```

The *declaration_pattern* both tests that an expression is of a given type and casts it to that type if the test succeeds. This may introduce a local variable of the given type named by the given identifier, if the designation is a *single_variable_designation*. That local variable is *definitely assigned* when the result of the pattern-matching operation is `true`.

The runtime semantic of this expression is that it tests the runtime type of the left-hand *relational_expression* operand against the *type* in the pattern. If it is of that runtime type (or some subtype) and not `null`, the result of the `is operator` is `true`.

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern-compatible* with a type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`, or if one of those types is an open type. It is a compile-time error if an input of type `E` is not *pattern-compatible* with the *type* in a type pattern that it is matched with.

The type pattern is useful for performing run-time type tests of reference types, and replaces the idiom

```
C#
```

```
var v = expr as Type;
if (v != null) { // code using v
```

With the slightly more concise

```
C#
```

```
if (expr is Type v) { // code using v
```

It is an error if *type* is a nullable value type.

The type pattern can be used to test values of nullable types: a value of type `Nullable<T>` (or a boxed `T`) matches a type pattern `T2 id` if the value is non-null and

the type of `T2` is `T`, or some base type or interface of `T`. For example, in the code fragment

```
C#  
  
int? x = 3;  
if (x is int v) { // code using v
```

The condition of the `if` statement is `true` at runtime and the variable `v` holds the value `3` of type `int` inside the block. After the block the variable `v` is in scope but not definitely assigned.

Constant Pattern

```
antlr  
  
constant_pattern  
    : constant_expression  
    ;
```

A constant pattern tests the value of an expression against a constant value. The constant may be any constant expression, such as a literal, the name of a declared `const` variable, or an enumeration constant. When the input value is not an open type, the constant expression is implicitly converted to the type of the matched expression; if the type of the input value is not *pattern-compatible* with the type of the constant expression, the pattern-matching operation is an error.

The pattern `c` is considered matching the converted input value `e` if `object.Equals(c, e)` would return `true`.

We expect to see `e is null` as the most common way to test for `null` in newly written code, as it cannot invoke a user-defined `operator==`.

Var Pattern

```
antlr  
  
var_pattern  
    : 'var' designation  
    ;  
designation  
    : simple_designation  
    | tuple_designation  
    ;
```

```

simple_designation
  : single_variable_designation
  | discard_designation
  ;
single_variable_designation
  : identifier
  ;
discard_designation
  : _
  ;
tuple_designation
  : '(' designations? ')'
  ;
designations
  : designation
  | designations ',' designation
  ;

```

If the *designation* is a *simple_designation*, an expression *e* matches the pattern. In other words, a match to a *var pattern* always succeeds with a *simple_designation*. If the *simple_designation* is a *single_variable_designation*, the value of *e* is bounds to a newly introduced local variable. The type of the local variable is the static type of *e*.

If the *designation* is a *tuple_designation*, then the pattern is equivalent to a *positional_pattern* of the form `(var designation, ...)` where the *designations* are those found within the *tuple_designation*. For example, the pattern `var (x, (y, z))` is equivalent to `(var x, (var y, var z))`.

It is an error if the name `var` binds to a type.

Discard Pattern

```

antlr

discard_pattern
  : '_'
  ;

```

An expression *e* matches the pattern `_` always. In other words, every expression matches the discard pattern.

A discard pattern may not be used as the pattern of an *is_pattern_expression*.

Positional Pattern

A positional pattern checks that the input value is not `null`, invokes an appropriate `Deconstruct` method, and performs further pattern matching on the resulting values. It also supports a tuple-like pattern syntax (without the type being provided) when the type of the input value is the same as the type containing `Deconstruct`, or if the type of the input value is a tuple type, or if the type of the input value is `object` or `ITuple` and the runtime type of the expression implements `ITuple`.

```
antlr
```

```
positional_pattern
    : type? '(' subpatterns? ')' property_subpattern? simple_designation?
    ;
subpatterns
    : subpattern
    | subpattern ',' subpatterns
    ;
subpattern
    : pattern
    | identifier ':' pattern
    ;
```

If the *type* is omitted, we take it to be the static type of the input value.

Given a match of an input value to the pattern *type* `(subpattern_list)`, a method is selected by searching in *type* for accessible declarations of `Deconstruct` and selecting one among them using the same rules as for the deconstruction declaration.

It is an error if a *positional_pattern* omits the *type*, has a single *subpattern* without an *identifier*, has no *property_subpattern* and has no *simple_designation*. This disambiguates between a *constant_pattern* that is parenthesized and a *positional_pattern*.

In order to extract the values to match against the patterns in the list,

- If *type* was omitted and the input value's type is a tuple type, then the number of subpatterns is required to be the same as the cardinality of the tuple. Each tuple element is matched against the corresponding *subpattern*, and the match succeeds if all of these succeed. If any *subpattern* has an *identifier*, then that must name a tuple element at the corresponding position in the tuple type.
- Otherwise, if a suitable `Deconstruct` exists as a member of *type*, it is a compile-time error if the type of the input value is not *pattern-compatible* with *type*. At runtime the input value is tested against *type*. If this fails then the positional pattern match fails. If it succeeds, the input value is converted to this type and `Deconstruct` is invoked with fresh compiler-generated variables to receive the `out` parameters. Each value that was received is matched against the corresponding *subpattern*, and

the match succeeds if all of these succeed. If any *subpattern* has an *identifier*, then that must name a parameter at the corresponding position of `Deconstruct`.

- Otherwise if *type* was omitted, and the input value is of type `object` or `ITuple` or some type that can be converted to `ITuple` by an implicit reference conversion, and no *identifier* appears among the subpatterns, then we match using `ITuple`.
- Otherwise the pattern is a compile-time error.

The order in which subpatterns are matched at runtime is unspecified, and a failed match may not attempt to match all subpatterns.

Example

This example uses many of the features described in this specification

c#

```
var newState = (GetState(), action, hasKey) switch {
    (DoorState.Closed, Action.Open, _) => DoorState.Opened,
    (DoorState.Opened, Action.Close, _) => DoorState.Closed,
    (DoorState.Closed, Action.Lock, true) => DoorState.Locked,
    (DoorState.Locked, Action.Unlock, true) => DoorState.Closed,
    (var state, _, _) => state };

```

Property Pattern

A property pattern checks that the input value is not `null` and recursively matches values extracted by the use of accessible properties or fields.

antlr

```
property_pattern
    : type? property_subpattern simple_designation?
    ;
property_subpattern
    : '{' '}'
    | '{' subpatterns ','? '}'
    ;

```

It is an error if any *subpattern* of a *property_pattern* does not contain an *identifier* (it must be of the second form, which has an *identifier*). A trailing comma after the last subpattern is optional.

Note that a null-checking pattern falls out of a trivial property pattern. To check if the string `s` is non-null, you can write any of the following forms

```
C#
```

```
if (s is object o) ... // o is of type object
if (s is string x) ... // x is of type string
if (s is {} x) ... // x is of type string
if (s is {}) ...
```

Given a match of an expression e to the pattern *type* `{ property_pattern_list }`, it is a compile-time error if the expression e is not *pattern-compatible* with the type T designated by *type*. If the type is absent, we take it to be the static type of e . If the *identifier* is present, it declares a pattern variable of type *type*. Each of the identifiers appearing on the left-hand-side of its *property_pattern_list* must designate an accessible readable property or field of T . If the *simple_designation* of the *property_pattern* is present, it defines a pattern variable of type T .

At runtime, the expression is tested against T . If this fails then the property pattern match fails and the result is `false`. If it succeeds, then each *property_subpattern* field or property is read and its value matched against its corresponding pattern. The result of the whole match is `false` only if the result of any of these is `false`. The order in which subpatterns are matched is not specified, and a failed match may not match all subpatterns at runtime. If the match succeeds and the *simple_designation* of the *property_pattern* is a *single_variable_designation*, it defines a variable of type T that is assigned the matched value.

Note: The property pattern can be used to pattern-match with anonymous types.

Example

```
C#
```

```
if (o is string { Length: 5 } s)
```

Switch Expression

A *switch_expression* is added to support `switch`-like semantics for an expression context.

The C# language syntax is augmented with the following syntactic productions:

```
antlr
```

```
multiplicative_expression
: switch_expression
| multiplicative_expression '*' switch_expression
```

```

    | multiplicative_expression '/' switch_expression
    | multiplicative_expression '%' switch_expression
    ;
switch_expression
: range_expression 'switch' '{' '}'
| range_expression 'switch' '{' switch_expression_arms ','? '}'
;
switch_expression_arms
: switch_expression_arm
| switch_expression_arms ',' switch_expression_arm
;
switch_expression_arm
: pattern case_guard? '=>' expression
;
case_guard
: 'when' null_coalescing_expression
;

```

The *switch_expression* is not permitted as an *expression_statement*.

We are looking at relaxing this in a future revision.

The type of the *switch_expression* is the *best common type* (§11.6.3.15) of the expressions appearing to the right of the `=>` tokens of the *switch_expression_arms* if such a type exists and the expression in every arm of the switch expression can be implicitly converted to that type. In addition, we add a new *switch expression conversion*, which is a predefined implicit conversion from a switch expression to every type `T` for which there exists an implicit conversion from each arm's expression to `T`.

It is an error if some *switch_expression_arm*'s pattern cannot affect the result because some previous pattern and guard will always match.

A switch expression is said to be *exhaustive* if some arm of the switch expression handles every value of its input. The compiler shall produce a warning if a switch expression is not *exhaustive*.

At runtime, the result of the *switch_expression* is the value of the *expression* of the first *switch_expression_arm* for which the expression on the left-hand-side of the *switch_expression* matches the *switch_expression_arm*'s pattern, and for which the *case_guard* of the *switch_expression_arm*, if present, evaluates to `true`. If there is no such *switch_expression_arm*, the *switch_expression* throws an instance of the exception `System.Runtime.CompilerServices.SwitchExpressionException`.

Optional parens when switching on a tuple literal

In order to switch on a tuple literal using the *switch_statement*, you have to write what appear to be redundant parens

```
C#  
  
switch ((a, b))  
{
```

To permit

```
C#  
  
switch (a, b)  
{
```

the parentheses of the switch statement are optional when the expression being switched on is a tuple literal.

Order of evaluation in pattern-matching

Giving the compiler flexibility in reordering the operations executed during pattern-matching can permit flexibility that can be used to improve the efficiency of pattern-matching. The (unenforced) requirement would be that properties accessed in a pattern, and the Deconstruct methods, are required to be "pure" (side-effect free, idempotent, etc). That doesn't mean that we would add purity as a language concept, only that we would allow the compiler flexibility in reordering operations.

Resolution 2018-04-04 LDM: confirmed: the compiler is permitted to reorder calls to `Deconstruct`, property accesses, and invocations of methods in `ITuple`, and may assume that returned values are the same from multiple calls. The compiler should not invoke functions that cannot affect the result, and we will be very careful before making any changes to the compiler-generated order of evaluation in the future.

Some Possible Optimizations

The compilation of pattern matching can take advantage of common parts of patterns. For example, if the top-level type test of two successive patterns in a *switch_statement* is the same type, the generated code can skip the type test for the second pattern.

When some of the patterns are integers or strings, the compiler can generate the same kind of code it generates for a switch-statement in earlier versions of the language.

For more on these kinds of optimizations, see [\[Scott and Ramsey \(2000\)\]](#).

default interface methods

Article • 2022-08-12 • 27 minutes to read

Summary

Add support for *virtual extension methods* - methods in interfaces with concrete implementations. A class or struct that implements such an interface is required to have a single *most specific* implementation for the interface method, either implemented by the class or struct, or inherited from its base classes or interfaces. Virtual extension methods enable an API author to add methods to an interface in future versions without breaking source or binary compatibility with existing implementations of that interface.

These are similar to Java's ["Default Methods"](#) [↗](#).

(Based on the likely implementation technique) this feature requires corresponding support in the CLI/CLR. Programs that take advantage of this feature cannot run on earlier versions of the platform.

Motivation

The principal motivations for this feature are

- Default interface methods enable an API author to add methods to an interface in future versions without breaking source or binary compatibility with existing implementations of that interface.
- The feature enables C# to interoperate with APIs targeting [Android \(Java\)](#) [↗](#) and [iOS \(Swift\)](#) [↗](#), which support similar features.
- As it turns out, adding default interface implementations provides the elements of the "traits" language feature ([https://en.wikipedia.org/wiki/Trait_\(computer_programming\)](https://en.wikipedia.org/wiki/Trait_(computer_programming)) [↗](#)). Traits have proven to be a powerful programming technique (<http://scg.unibe.ch/archive/papers/Scha03aTraits.pdf> [↗](#)).

Detailed design

The syntax for an interface is extended to permit

- member declarations that declare constants, operators, static constructors, and nested types;

- a *body* for a method or indexer, property, or event accessor (that is, a "default" implementation);
- member declarations that declare static fields, methods, properties, indexers, and events;
- member declarations using the explicit interface implementation syntax; and
- Explicit access modifiers (the default access is `public`).

Members with bodies permit the interface to provide a "default" implementation for the method in classes and structs that do not provide their own implementation.

Interfaces may not contain instance state. While static fields are now permitted, instance fields are not permitted in interfaces. Instance auto-properties are not supported in interfaces, as they would implicitly declare a hidden field.

Static and private methods permit useful refactoring and organization of code used to implement the interface's public API.

A method override in an interface must use the explicit interface implementation syntax.

It is an error to declare a class type, struct type, or enum type within the scope of a type parameter that was declared with a *variance_annotation*. For example, the declaration of `C` below is an error.

C#

```
interface IOuter<out T>
{
    class C { } // error: class declaration within the scope of variant type
    parameter 'T'
}
```

Concrete methods in interfaces

The simplest form of this feature is the ability to declare a *concrete method* in an interface, which is a method with a body.

C#

```
interface IA
{
    void M() { WriteLine("IA.M"); }
}
```

A class that implements this interface need not implement its concrete method.

C#

```
class C : IA { } // OK

IA i = new C();
i.M(); // prints "IA.M"
```

The final override for `IA.M` in class `C` is the concrete method `M` declared in `IA`. Note that a class does not inherit members from its interfaces; that is not changed by this feature:

C#

```
new C().M(); // error: class 'C' does not contain a member 'M'
```

Within an instance member of an interface, `this` has the type of the enclosing interface.

Modifiers in interfaces

The syntax for an interface is relaxed to permit modifiers on its members. The following are permitted: `private`, `protected`, `internal`, `public`, `virtual`, `abstract`, `sealed`, `static`, `extern`, and `partial`.

TODO: check what other modifiers exist.

An interface member whose declaration includes a body is a `virtual` member unless the `sealed` or `private` modifier is used. The `virtual` modifier may be used on a function member that would otherwise be implicitly `virtual`. Similarly, although `abstract` is the default on interface members without bodies, that modifier may be given explicitly. A non-virtual member may be declared using the `sealed` keyword.

It is an error for a `private` or `sealed` function member of an interface to have no body. A `private` function member may not have the modifier `sealed`.

Access modifiers may be used on interface members of all kinds of members that are permitted. The access level `public` is the default but it may be given explicitly.

Open Issue: We need to specify the precise meaning of the access modifiers such as `protected` and `internal`, and which declarations do and do not override them (in a derived interface) or implement them (in a class that implements the interface).

Interfaces may declare `static` members, including nested types, methods, indexers, properties, events, and static constructors. The default access level for all interface members is `public`.

Interfaces may not declare instance constructors, destructors, or fields.

Closed Issue: Should operator declarations be permitted in an interface? Probably not conversion operators, but what about others? **Decision:** Operators are permitted *except* for conversion, equality, and inequality operators.

Closed Issue: Should `new` be permitted on interface member declarations that hide members from base interfaces? **Decision:** Yes.

Closed Issue: We do not currently permit `partial` on an interface or its members. That would require a separate proposal. **Decision:** Yes.

<https://github.com/dotnet/csharpplang/blob/master/meetings/2018/LDM-2018-10-17.md#permit-partial-in-interface> ↗

Explicit implementation in interfaces

Explicit implementations allow the programmer to provide a most specific implementation of a virtual member in an interface where the compiler or runtime would not otherwise find one. An implementation declaration is permitted to *explicitly* implement a particular base interface method by qualifying the declaration with the interface name (no access modifier is permitted in this case). Implicit implementations are not permitted.

```
C#  
  
interface IA  
{  
    void M() { WriteLine("IA.M"); }  
}  
interface IB : IA  
{  
    void IA.M() { WriteLine("IB.M"); } // Explicit implementation  
}  
interface IC : IA  
{  
    void M() { WriteLine("IC.M"); } // Creates a new M, unrelated to `IA.M`.  
    Warning  
}
```

Explicit implementations in interfaces may not be declared `sealed`.

Public `virtual` function members in an interface may only be implemented in a derived interface explicitly (by qualifying the name in the declaration with the interface type that originally declared the method, and omitting an access modifier). The member must be *accessible* where it is implemented.

Reabstraction

A virtual (concrete) method declared in an interface may be reabstracted in a derived interface

```
C#  
  
interface IA  
{  
    void M() { WriteLine("IA.M"); }  
}  
interface IB : IA  
{  
    abstract void IA.M();  
}  
class C : IB { } // error: class 'C' does not implement 'IA.M'.
```

The `abstract` modifier is required in the declaration of `IB.M`, to indicate that `IA.M` is being reabstracted.

This is useful in derived interfaces where the default implementation of a method is inappropriate and a more appropriate implementation should be provided by implementing classes.

Open Issue: Should reabstraction be permitted?

The most specific implementation rule

We require that every interface and class have a *most specific implementation* for every virtual member among the implementations appearing in the type or its direct and indirect interfaces. The *most specific implementation* is a unique implementation that is more specific than every other implementation. If there is no implementation, the member itself is considered the most specific implementation.

One implementation `M1` is considered *more specific* than another implementation `M2` if `M1` is declared on type `T1`, `M2` is declared on type `T2`, and either

1. `T1` contains `T2` among its direct or indirect interfaces, or
2. `T2` is an interface type but `T1` is not an interface type.

For example:

```
C#  
  
interface IA  
{  
    void M() { WriteLine("IA.M"); }  
}  
interface IB : IA  
{  
    void IA.M() { WriteLine("IB.M"); }  
}  
interface IC : IA  
{  
    void IA.M() { WriteLine("IC.M"); }  
}  
interface ID : IB, IC { } // error: no most specific implementation for  
'IA.M'  
abstract class C : IB, IC { } // error: no most specific implementation for  
'IA.M'  
abstract class D : IA, IB, IC // ok  
{  
    public abstract void M();  
}
```

The most specific implementation rule ensures that a conflict (i.e. an ambiguity arising from diamond inheritance) is resolved explicitly by the programmer at the point where the conflict arises.

Because we support explicit reabstractions in interfaces, we could do so in classes as well

```
C#  
  
abstract class E : IA, IB, IC // ok  
{  
    abstract void IA.M();  
}
```

Open issue: should we support explicit interface abstract implementations in classes?

In addition, it is an error if in a class declaration the most specific implementation of some interface method is an abstract implementation that was declared in an interface. This is an existing rule restated using the new terminology.

```
C#
```

```
interface IF
{
    void M();
}
abstract class F : IF { } // error: 'F' does not implement 'IF.M'
```

It is possible for a virtual property declared in an interface to have a most specific implementation for its `get` accessor in one interface and a most specific implementation for its `set` accessor in a different interface. This is considered a violation of the *most specific implementation* rule.

static and private methods

Because interfaces may now contain executable code, it is useful to abstract common code into private and static methods. We now permit these in interfaces.

Closed issue: Should we support private methods? Should we support static methods? **Decision:** YES

Open issue: should we permit interface methods to be `protected` or `internal` or other access? If so, what are the semantics? Are they `virtual` by default? If so, is there a way to make them non-virtual?

Open issue: If we support static methods, should we support (static) operators?

Base interface invocations

Code in a type that derives from an interface with a default method can explicitly invoke that interface's "base" implementation.

```
C#

interface I0
{
    void M() { Console.WriteLine("I0"); }
}
interface I1 : I0
{
    override void M() { Console.WriteLine("I1"); }
}
interface I2 : I0
{
    override void M() { Console.WriteLine("I2"); }
}
```

```
interface I3 : I1, I2
{
    // an explicit override that invoke's a base interface's default method
    void I0.M() { I2.base.M(); }
}
```

An instance (nonstatic) method is permitted to invoke the implementation of an accessible instance method in a direct base interface nonvirtually by naming it using the syntax `base(Type).M`. This is useful when an override that is required to be provided due to diamond inheritance is resolved by delegating to one particular base implementation.

```
C#

interface IA
{
    void M() { WriteLine("IA.M"); }
}
interface IB : IA
{
    override void IA.M() { WriteLine("IB.M"); }
}
interface IC : IA
{
    override void IA.M() { WriteLine("IC.M"); }
}

class D : IA, IB, IC
{
    void IA.M() { base(IB).M(); }
}
```

When a `virtual` or `abstract` member is accessed using the syntax `base(Type).M`, it is required that `Type` contains a unique *most specific override* for `M`.

Binding base clauses

Interfaces now contain types. These types may be used in the base clause as base interfaces. When binding a base clause, we may need to know the set of base interfaces to bind those types (e.g. to lookup in them and to resolve protected access). The meaning of an interface's base clause is thus circularly defined. To break the cycle, we add a new language rules corresponding to a similar rule already in place for classes.

While determining the meaning of the *interface_base* of an interface, the base interfaces are temporarily assumed to be empty. Intuitively this ensures that the meaning of a base clause cannot recursively depend on itself.

We used to have the following rules:

"When a class B derives from a class A, it is a compile-time error for A to depend on B. A class **directly depends on** its direct base class (if any) and **directly depends on** the **class** within which it is immediately nested (if any). Given this definition, the complete set of **classes** upon which a class depends is the reflexive and transitive closure of the **directly depends on** relationship."

It is a compile-time error for an interface to directly or indirectly inherit from itself. The **base interfaces** of an interface are the explicit base interfaces and their base interfaces. In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on.

We are adjusting them as follows:

When a class B derives from a class A, it is a compile-time error for A to depend on B. A class **directly depends on** its direct base class (if any) and **directly depends on** the **type** within which it is immediately nested (if any).

When an interface IB extends an interface IA, it is a compile-time error for IA to depend on IB. An interface **directly depends on** its direct base interfaces (if any) and **directly depends on** the type within which it is immediately nested (if any).

Given these definitions, the complete set of **types** upon which a type depends is the reflexive and transitive closure of the **directly depends on** relationship.

Effect on existing programs

The rules presented here are intended to have no effect on the meaning of existing programs.

Example 1:

```
C#  
  
interface IA  
{  
    void M();  
}  
class C: IA // Error: IA.M has no concrete most specific override in C  
{  
    public static void M() { } // method unrelated to 'IA.M' because static  
}
```

Example 2:

C#

```
interface IA
{
    void M();
}
class Base: IA
{
    void IA.M() { }
}
class Derived: Base, IA // OK, all interface members have a concrete most
specific override
{
    private void M() { } // method unrelated to 'IA.M' because private
}
```

The same rules give similar results to the analogous situation involving default interface methods:

C#

```
interface IA
{
    void M() { }
}
class Derived: IA // OK, all interface members have a concrete most specific
override
{
    private void M() { } // method unrelated to 'IA.M' because private
}
```

Closed issue: confirm that this is an intended consequence of the specification.

Decision: YES

Runtime method resolution

Closed Issue: The spec should describe the runtime method resolution algorithm in the face of interface default methods. We need to ensure that the semantics are consistent with the language semantics, e.g. which declared methods do and do not override or implement an `internal` method.

CLR support API

In order for compilers to detect when they are compiling for a runtime that supports this feature, libraries for such runtimes are modified to advertise that fact through the API discussed in <https://github.com/dotnet/corefx/issues/17116>. We add

C#

```
namespace System.Runtime.CompilerServices
{
    public static class RuntimeFeature
    {
        // Presence of the field indicates runtime support
        public const string DefaultInterfaceImplementation =
nameof(DefaultInterfaceImplementation);
    }
}
```

Open issue: Is that the best name for the CLR feature? The CLR feature does much more than just that (e.g. relaxes protection constraints, supports overrides in interfaces, etc). Perhaps it should be called something like "concrete methods in interfaces", or "traits"?

Further areas to be specified

- [] It would be useful to catalog the kinds of source and binary compatibility effects caused by adding default interface methods and overrides to existing interfaces.

Drawbacks

This proposal requires a coordinated update to the CLR specification (to support concrete methods in interfaces and method resolution). It is therefore fairly "expensive" and it may be worth doing in combination with other features that we also anticipate would require CLR changes.

Alternatives

None.

Unresolved questions

- Open questions are called out throughout the proposal, above.
- See also <https://github.com/dotnet/csharplang/issues/406> for a list of open questions.
- The detailed specification must describe the resolution mechanism used at runtime to select the precise method to be invoked.

- The interaction of metadata produced by new compilers and consumed by older compilers needs to be worked out in detail. For example, we need to ensure that the metadata representation that we use does not cause the addition of a default implementation in an interface to break an existing class that implements that interface when compiled by an older compiler. This may affect the metadata representation that we can use.
- The design must consider interoperability with other languages and existing compilers for other languages.

Resolved Questions

Abstract Override

The earlier draft spec contained the ability to "reabstract" an inherited method:

C#

```
interface IA
{
    void M();
}
interface IB : IA
{
    override void M() { }
}
interface IC : IB
{
    override void M(); // make it abstract again
}
```

My notes for 2017-03-20 showed that we decided not to allow this. However, there are at least two use cases for it:

1. The Java APIs, with which some users of this feature hope to interoperate, depend on this facility.
2. Programming with *traits* benefits from this. Reabstraction is one of the elements of the "traits" language feature ([https://en.wikipedia.org/wiki/Trait_\(computer_programming\)|](https://en.wikipedia.org/wiki/Trait_(computer_programming)|)). The following is permitted with classes:

C#

```
public abstract class Base
{
    public abstract void M();
}
```

```
}  
public abstract class A : Base  
{  
    public override void M() { }  
}  
public abstract class B : A  
{  
    public override abstract void M(); // reabstract Base.M  
}
```

Unfortunately this code cannot be refactored as a set of interfaces (traits) unless this is permitted. By the *Jared principle of greed*, it should be permitted.

Closed issue: Should reabstraction be permitted? [YES] My notes were wrong. The [LDM notes](#) say that reabstraction is permitted in an interface. Not in a class.

Virtual Modifier vs Sealed Modifier

From [Aleksey Tsingauz](#):

We decided to allow modifiers explicitly stated on interface members, unless there is a reason to disallow some of them. This brings an interesting question around virtual modifier. Should it be required on members with default implementation?

We could say that:

- if there is no implementation and neither virtual, nor sealed are specified, we assume the member is abstract.
- if there is an implementation and neither abstract, nor sealed are specified, we assume the member is virtual.
- sealed modifier is required to make a method neither virtual, nor abstract.

Alternatively, we could say that virtual modifier is required for a virtual member. I.e, if there is a member with implementation not explicitly marked with virtual modifier, it is neither virtual, nor abstract. This approach might provide better experience when a method is moved from a class to an interface:

- an abstract method stays abstract.
- a virtual method stays virtual.
- a method without any modifier stays neither virtual, nor abstract.
- sealed modifier cannot be applied to a method that is not an override.

What do you think?

Closed Issue: Should a concrete method (with implementation) be implicitly `virtual`? [YES]

Decisions: Made in the LDM 2017-04-05:

1. non-virtual should be explicitly expressed through `sealed` or `private`.
2. `sealed` is the keyword to make interface instance members with bodies non-virtual
3. We want to allow all modifiers in interfaces
4. Default accessibility for interface members is public, including nested types
5. private function members in interfaces are implicitly sealed, and `sealed` is not permitted on them.
6. Private classes (in interfaces) are permitted and can be sealed, and that means sealed in the class sense of sealed.
7. Absent a good proposal, partial is still not allowed on interfaces or their members.

Binary Compatibility 1

When a library provides a default implementation

```
C#  
  
interface I1  
{  
    void M() { Impl1 }  
}  
interface I2 : I1  
{  
}  
class C : I2  
{  
}
```

We understand that the implementation of `I1.M` in `C` is `I1.M`. What if the assembly containing `I2` is changed as follows and recompiled

```
C#  
  
interface I2 : I1  
{  
    override void M() { Impl2 }  
}
```

but `C` is not recompiled. What happens when the program is run? An invocation of `C` as `I1.M()`

1. Runs I1.M
2. Runs I2.M
3. Throws some kind of runtime error

Decision: Made 2017-04-11: Runs I2.M, which is the unambiguously most specific override at runtime.

Event accessors (closed)

Closed Issue: Can an event be overridden "piecewise"?

Consider this case:

```
C#  
  
public interface I1  
{  
    event T e1;  
}  
public interface I2 : I1  
{  
    override event T  
    {  
        add { }  
        // error: "remove" accessor missing  
    }  
}
```

This "partial" implementation of the event is not permitted because, as in a class, the syntax for an event declaration does not permit only one accessor; both (or neither) must be provided. You could accomplish the same thing by permitting the abstract remove accessor in the syntax to be implicitly abstract by the absence of a body:

```
C#  
  
public interface I1  
{  
    event T e1;  
}  
public interface I2 : I1  
{  
    override event T  
    {  
        add { }  
        remove; // implicitly abstract  
    }  
}
```

Note that *this is a new (proposed) syntax*. In the current grammar, event accessors have a mandatory body.

Closed Issue: Can an event accessor be (implicitly) abstract by the omission of a body, similarly to the way that methods in interfaces and property accessors are (implicitly) abstract by the omission of a body?

Decision: (2017-04-18) No, event declarations require both concrete accessors (or neither).

Reabstraction in a Class (closed)

Closed Issue: We should confirm that this is permitted (otherwise adding a default implementation would be a breaking change):

```
C#  
  
interface I1  
{  
    void M() { }  
}  
abstract class C : I1  
{  
    public abstract void M(); // implement I1.M with an abstract method in C  
}
```

Decision: (2017-04-18) Yes, adding a body to an interface member declaration shouldn't break C.

Sealed Override (closed)

The previous question implicitly assumes that the `sealed` modifier can be applied to an `override` in an interface. This contradicts the draft specification. Do we want to permit sealing an override? Source and binary compatibility effects of sealing should be considered.

Closed Issue: Should we permit sealing an override?

Decision: (2017-04-18) Let's not allowed `sealed` on overrides in interfaces. The only use of `sealed` on interface members is to make them non-virtual in their initial declaration.

Diamond inheritance and classes (closed)

The draft of the proposal prefers class overrides to interface overrides in diamond inheritance scenarios:

We require that every interface and class have a *most specific override* for every interface method among the overrides appearing in the type or its direct and indirect interfaces. The *most specific override* is a unique override that is more specific than every other override. If there is no override, the method itself is considered the most specific override.

One override `M1` is considered *more specific* than another override `M2` if `M1` is declared on type `T1`, `M2` is declared on type `T2`, and either

1. `T1` contains `T2` among its direct or indirect interfaces, or
2. `T2` is an interface type but `T1` is not an interface type.

The scenario is this

```
C#  
  
interface IA  
{  
    void M();  
}  
interface IB : IA  
{  
    override void M() { WriteLine("IB"); }  
}  
class Base : IA  
{  
    void IA.M() { WriteLine("Base"); }  
}  
class Derived : Base, IB // allowed?  
{  
    static void Main()  
    {  
        IA a = new Derived();  
        a.M();           // what does it do?  
    }  
}
```

We should confirm this behavior (or decide otherwise)

Closed Issue: Confirm the draft spec, above, for *most specific override* as it applies to mixed classes and interfaces (a class takes priority over an interface). See

<https://github.com/dotnet/csharp-lang/blob/master/meetings/2017/LDM-2017-04-19.md#diamonds-with-classes>.

Interface methods vs structs (closed)

There are some unfortunate interactions between default interface methods and structs.

C#

```
interface IA
{
    public void M() { }
}
struct S : IA
{
}
```

Note that interface members are not inherited:

C#

```
var s = default(S);
s.M(); // error: 'S' does not contain a member 'M'
```

Consequently, the client must box the struct to invoke interface methods

C#

```
IA s = default(S); // an S, boxed
s.M(); // ok
```

Boxing in this way defeats the principal benefits of a `struct` type. Moreover, any mutation methods will have no apparent effect, because they are operating on a *boxed copy* of the struct:

C#

```
interface IB
{
    public void Increment() { P += 1; }
    public int P { get; set; }
}
struct T : IB
{
    public int P { get; set; } // auto-property
}
```

```
T t = default(T);
Console.WriteLine(t.P); // prints 0
(t as IB).Increment();
Console.WriteLine(t.P); // prints 0
```

Closed Issue: What can we do about this:

1. Forbid a `struct` from inheriting a default implementation. All interface methods would be treated as abstract in a `struct`. Then we may take time later to decide how to make it work better.
2. Come up with some kind of code generation strategy that avoids boxing. Inside a method like `IB.Increment`, the type of `this` would perhaps be akin to a type parameter constrained to `IB`. In conjunction with that, to avoid boxing in the caller, non-abstract methods would be inherited from interfaces. This may increase compiler and CLR implementation work substantially.
3. Not worry about it and just leave it as a wart.
4. Other ideas?

Decision: Not worry about it and just leave it as a wart. See

<https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-19.md#structs-and-default-implementations>.

Base interface invocations (closed)

The draft spec suggests a syntax for base interface invocations inspired by Java:

`Interface.base.M()`. We need to select a syntax, at least for the initial prototype. My favorite is `base<Interface>.M()`.

Closed Issue: What is the syntax for a base member invocation?

Decision: The syntax is `base(Interface).M()`. See

<https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-19.md#base-invocation>. The interface so named must be a base interface, but does not need to be a direct base interface.

Open Issue: Should base interface invocations be permitted in class members?

Decision: Yes. <https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-19.md#base-invocation>

Overriding non-public interface members (closed)

In an interface, non-public members from base interfaces are overridden using the `override` modifier. If it is an "explicit" override that names the interface containing the member, the access modifier is omitted.

Closed Issue: If it is an "implicit" override that does not name the interface, does the access modifier have to match?

Decision: Only public members may be implicitly overridden, and the access must match. See <https://github.com/dotnet/csharp-lang/blob/master/meetings/2017/LDM-2017-04-18.md#dim-implementing-a-non-public-interface-member-not-in-list>.

Open Issue: Is the access modifier required, optional, or omitted on an explicit override such as `override void IB.M() {}`?

Open Issue: Is `override` required, optional, or omitted on an explicit override such as `void IB.M() {}`?

How does one implement a non-public interface member in a class? Perhaps it must be done explicitly?

```
C#  
  
interface IA  
{  
    internal void MI();  
    protected void MP();  
}  
class C : IA  
{  
    // are these implementations?  
    internal void MI() {}  
    protected void MP() {}  
}
```

Closed Issue: How does one implement a non-public interface member in a class?

Decision: You can only implement non-public interface members explicitly. See <https://github.com/dotnet/csharp-lang/blob/master/meetings/2017/LDM-2017-04-18.md#dim-implementing-a-non-public-interface-member-not-in-list>.

Decision: No `override` keyword permitted on interface members.

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#does-an-override-in-an-interface-introduce-a-new-member> ↗

Binary Compatibility 2 (closed)

Consider the following code in which each type is in a separate assembly

```
C#  
  
interface I1  
{  
    void M() { Impl1 }  
}  
interface I2 : I1  
{  
    override void M() { Impl2 }  
}  
interface I3 : I1  
{  
}  
class C : I2, I3  
{  
}
```

We understand that the implementation of `I1.M` in `C` is `I2.M`. What if the assembly containing `I3` is changed as follows and recompiled

```
C#  
  
interface I3 : I1  
{  
    override void M() { Impl3 }  
}
```

but `C` is not recompiled. What happens when the program is run? An invocation of `(C as I1).M()`

1. Runs `I1.M`
2. Runs `I2.M`
3. Runs `I3.M`
4. Either 2 or 3, deterministically
5. Throws some kind of runtime exception

Decision: Throw an exception (5). See

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#does-an-override-in-an-interface-introduce-a-new-member>

[17.md#issues-in-default-interface-methods](#) ↗.

Permit `partial` in interface? (closed)

Given that interfaces may be used in ways analogous to the way abstract classes are used, it may be useful to declare them `partial`. This would be particularly useful in the face of generators.

Proposal: Remove the language restriction that interfaces and members of interfaces may not be declared `partial`.

Decision: Yes. See

<https://github.com/dotnet/csharp-lang/blob/master/meetings/2018/LDM-2018-10-17.md#permit-partial-in-interface> ↗.

Main in an interface? (closed)

Open Issue: Is a `static Main` method in an interface a candidate to be the program's entry point?

Decision: Yes. See

<https://github.com/dotnet/csharp-lang/blob/master/meetings/2018/LDM-2018-10-17.md#main-in-an-interface> ↗.

Confirm intent to support public non-virtual methods (closed)

Can we please confirm (or reverse) our decision to permit non-virtual public methods in an interface?

```
C#
```

```
interface IA
{
    public sealed void M() { }
}
```

Semi-Closed Issue: (2017-04-18) We think it is going to be useful, but will come back to it. This is a mental model tripping block.

Decision: Yes. <https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#confirm-that-we-support-public-non-virtual-methods> ↗.

Does an `override` in an interface introduce a new member? (closed)

There are a few ways to observe whether an override declaration introduces a new member or not.

C#

```
interface IA
{
    void M(int x) { }
}
interface IB : IA
{
    override void M(int y) { }
}
interface IC : IB
{
    static void M2()
    {
        M(y: 3); // permitted?
    }
    override void IB.M(int z) { } // permitted? What does it override?
}
```

Open Issue: Does an override declaration in an interface introduce a new member?
(closed)

In a class, an overriding method is "visible" in some senses. For example, the names of its parameters take precedence over the names of parameters in the overridden method. It may be possible to duplicate that behavior in interfaces, as there is always a most specific override. But do we want to duplicate that behavior?

Also, it is possible to "override" an override method? [Moot]

Decision: No `override` keyword permitted on interface members.

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#does-an-override-in-an-interface-introduce-a-new-member> ↗.

Properties with a private accessor (closed)

We say that private members are not virtual, and the combination of virtual and private is disallowed. But what about a property with a private accessor?

```
C#  
  
interface IA  
{  
    public virtual int P  
    {  
        get => 3;  
        private set => { }  
    }  
}
```

Is this allowed? Is the `set` accessor here `virtual` or not? Can it be overridden where it is accessible? Does the following implicitly implement only the `get` accessor?

```
C#  
  
class C : IA  
{  
    public int P  
    {  
        get => 4;  
        set { }  
    }  
}
```

Is the following presumably an error because `IA.P.set` isn't virtual and also because it isn't accessible?

```
C#  
  
class C : IA  
{  
    int IA.P  
    {  
        get => 4;  
        set { }  
    }  
}
```

Decision: The first example looks valid, while the last does not. This is resolved analogously to how it already works in C#.

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#properties-with-a-private-accessor>

Base Interface Invocations, round 2 (closed)

Our previous "resolution" to how to handle base invocations doesn't actually provide sufficient expressiveness. It turns out that in C# and the CLR, unlike Java, you need to specify both the interface containing the method declaration and the location of the implementation you want to invoke.

I propose the following syntax for base calls in interfaces. I'm not in love with it, but it illustrates what any syntax must be able to express:

C#

```
interface I1 { void M(); }
interface I2 { void M(); }
interface I3 : I1, I2 { void I1.M() { } void I2.M() { } }
interface I4 : I1, I2 { void I1.M() { } void I2.M() { } }
interface I5 : I3, I4
{
    void I1.M()
    {
        base<I3>(I1).M(); // calls I3's implementation of I1.M
        base<I4>(I1).M(); // calls I4's implementation of I1.M
    }
    void I2.M()
    {
        base<I3>(I2).M(); // calls I3's implementation of I2.M
        base<I4>(I2).M(); // calls I4's implementation of I2.M
    }
}
```

If there is no ambiguity, you can write it more simply

C#

```
interface I1 { void M(); }
interface I3 : I1 { void I1.M() { } }
interface I4 : I1 { void I1.M() { } }
interface I5 : I3, I4
{
    void I1.M()
    {
        base<I3>.M(); // calls I3's implementation of I1.M
        base<I4>.M(); // calls I4's implementation of I1.M
    }
}
```

Or

C#

```

interface I1 { void M(); }
interface I2 { void M(); }
interface I3 : I1, I2 { void I1.M() { } void I2.M() { } }
interface I5 : I3
{
    void I1.M()
    {
        base(I1).M(); // calls I3's implementation of I1.M
    }
    void I2.M()
    {
        base(I2).M(); // calls I3's implementation of I2.M
    }
}

```

Or

```

C#
interface I1 { void M(); }
interface I3 : I1 { void I1.M() { } }
interface I5 : I3
{
    void I1.M()
    {
        base.M(); // calls I3's implementation of I1.M
    }
}

```

Decision: Decided on `base(N.I1<T>).M(s)`, conceding that if we have an invocation binding there may be problem here later on.

Warning for struct not implementing default method? (closed)

@vancem asserts that we should seriously consider producing a warning if a value type declaration fails to override some interface method, even if it would inherit an implementation of that method from an interface. Because it causes boxing and undermines constrained calls.

Decision: This seems like something more suited for an analyzer. It also seems like this warning could be noisy, since it would fire even if the default interface method is never called and no boxing will ever occur.

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#warning-for-struct-not-implementing-default-method> ↗

Interface static constructors (closed)

When are interface static constructors run? The current CLI draft proposes that it occurs when the first static method or field is accessed. If there are neither of those then it might never be run??

[2018-10-09 The CLR team proposes "Going to mirror what we do for valuetypes (cctor check on access to each instance method)"]

Decision: Static constructors are also run on entry to instance methods, if the static constructor was not `beforefieldinit`, in which case static constructors are run before access to the first static field.

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#when-are-interface-static-constructors-run> ↗

Async Streams

Article • 2022-10-11 • 21 minutes to read

Summary

C# has support for iterator methods and async methods, but no support for a method that is both an iterator and an async method. We should rectify this by allowing for `await` to be used in a new form of `async` iterator, one that returns an `IAsyncEnumerable<T>` or `IAsyncEnumerator<T>` rather than an `IEnumerable<T>` or `IEnumerator<T>`, with `IAsyncEnumerable<T>` consumable in a new `await foreach`. An `IAsyncDisposable` interface is also used to enable asynchronous cleanup.

- <https://github.com/dotnet/roslyn/issues/114> ↗

Detailed design

Interfaces

`IAsyncDisposable`

There has been much discussion of `IAsyncDisposable` (e.g. <https://github.com/dotnet/roslyn/issues/114> ↗) and whether it's a good idea. However, it's a required concept to add in support of async iterators. Since `finally` blocks may contain `await`s, and since `finally` blocks need to be run as part of disposing of iterators, we need async disposal. It's also just generally useful any time cleaning up of resources might take any period of time, e.g. closing files (requiring flushes), deregistering callbacks and providing a way to know when deregistration has completed, etc.

The following interface is added to the core .NET libraries (e.g. `System.Private.CoreLib` / `System.Runtime`):

C#

```

namespace System
{
    public interface IAsyncDisposable
    {
        ValueTask DisposeAsync();
    }
}

```

As with `Dispose`, invoking `DisposeAsync` multiple times is acceptable, and subsequent invocations after the first should be treated as nops, returning a synchronously completed successful task (`DisposeAsync` need not be thread-safe, though, and need not support concurrent invocation). Further, types may implement both `IDisposable` and `IAsyncDisposable`, and if they do, it's similarly acceptable to invoke `Dispose` and then `DisposeAsync` or vice versa, but only the first should be meaningful and subsequent invocations of either should be a nop. As such, if a type does implement both, consumers are encouraged to call once and only once the more relevant method based on the context, `Dispose` in synchronous contexts and `DisposeAsync` in asynchronous ones.

(I'm leaving discussion of how `IAsyncDisposable` interacts with `using` to a separate discussion. And coverage of how it interacts with `foreach` is handled later in this proposal.)

Alternatives considered:

- `DisposeAsync` accepting a `CancellationToken`: while in theory it makes sense that anything async can be canceled, disposal is about cleanup, closing things out, free'ing resources, etc., which is generally not something that should be canceled; cleanup is still important for work that's canceled. The same `CancellationToken` that caused the actual work to be canceled would typically be the same token passed to `DisposeAsync`, making `DisposeAsync` worthless because cancellation of the work would cause `DisposeAsync` to be a nop. If someone wants to avoid being blocked waiting for disposal, they can avoid waiting on the resulting `ValueTask`, or wait on it only for some period of time.
- `DisposeAsync` returning a `Task`: Now that a non-generic `ValueTask` exists and can be constructed from an `IValueTaskSource`, returning `ValueTask` from `DisposeAsync` allows an existing object to be reused as the promise representing the eventual async completion of `DisposeAsync`, saving a `Task` allocation in the case where `DisposeAsync` completes asynchronously.
- *Configuring `DisposeAsync` with a `bool continueOnCapturedContext` (`ConfigureAwait`):* While there may be issues related to how such a concept is

exposed to `using`, `foreach`, and other language constructs that consume this, from an interface perspective it's not actually doing any `await`'ing and there's nothing to configure... consumers of the `ValueTask` can consume it however they wish.

- `IAsyncDisposable` inheriting `IDisposable`: Since only one or the other should be used, it doesn't make sense to force types to implement both.
- `IDisposableAsync` instead of `IAsyncDisposable`: We've been following the naming that things/types are an "async something" whereas operations are "done async", so types have "Async" as a prefix and methods have "Async" as a suffix.

IAsyncEnumerable / IAsyncEnumerator

Two interfaces are added to the core .NET libraries:

```
C#  
  
namespace System.Collections.Generic  
{  
    public interface IAsyncEnumerable<out T>  
    {  
        IAsyncEnumerator<T> GetAsyncEnumerator(CancellationTok  
cancellationToken = default);  
    }  
  
    public interface IAsyncEnumerator<out T> : IAsyncDisposable  
    {  
        ValueTask<bool> MoveNextAsync();  
        T Current { get; }  
    }  
}
```

Typical consumption (without additional language features) would look like:

```
C#  
  
IAsyncEnumerator<T> enumerator = enumerable.GetAsyncEnumerator();  
try  
{  
    while (await enumerator.MoveNextAsync())  
    {  
        Use(enumerator.Current);  
    }  
}  
finally { await enumerator.DisposeAsync(); }
```

Discarded options considered:

- `Task<bool> MoveNextAsync(); T current { get; };` Using `Task<bool>` would support using a cached task object to represent synchronous, successful `MoveNextAsync` calls, but an allocation would still be required for asynchronous completion. By returning `ValueTask<bool>`, we enable the enumerator object to itself implement `IValueTaskSource<bool>` and be used as the backing for the `ValueTask<bool>` returned from `MoveNextAsync`, which in turn allows for significantly reduced overheads.
- `ValueTask<(bool, T)> MoveNextAsync();` It's not only harder to consume, but it means that `T` can no longer be covariant.
- `ValueTask<T?> TryMoveNextAsync();` Not covariant.
- `Task<T?> TryMoveNextAsync();` Not covariant, allocations on every call, etc.
- `ITask<T?> TryMoveNextAsync();` Not covariant, allocations on every call, etc.
- `ITask<(bool, T)> TryMoveNextAsync();` Not covariant, allocations on every call, etc.
- `Task<bool> TryMoveNextAsync(out T result);` The `out` result would need to be set when the operation returns synchronously, not when it asynchronously completes the task potentially sometime long in the future, at which point there'd be no way to communicate the result.
- `IAsyncEnumerator<T>` not implementing `IAsyncDisposable`: We could choose to separate these. However, doing so complicates certain other areas of the proposal, as code must then be able to deal with the possibility that an enumerator doesn't provide disposal, which makes it difficult to write pattern-based helpers. Further, it will be common for enumerators to have a need for disposal (e.g. any C# async iterator that has a finally block, most things enumerating data from a network connection, etc.), and if one doesn't, it is simple to implement the method purely as `public ValueTask DisposeAsync() => default(ValueTask);` with minimal additional overhead.
- `_ IAsyncEnumerator<T> GetAsyncEnumerator();` No cancellation token parameter.

Viable alternative:

C#

```
namespace System.Collections.Generic
{
    public interface IAsyncEnumerable<out T>
    {
        IAsyncEnumerator<T> GetAsyncEnumerator();
    }

    public interface IAsyncEnumerator<out T> : IAsyncDisposable
    {
        ValueTask<bool> WaitForNextAsync();
    }
}
```

```
        T TryGetNext(out bool success);
    }
}
```

`TryGetNext` is used in an inner loop to consume items with a single interface call as long as they're available synchronously. When the next item can't be retrieved synchronously, it returns false, and any time it returns false, a caller must subsequently invoke `WaitForNextAsync` to either wait for the next item to be available or to determine that there will never be another item. Typical consumption (without additional language features) would look like:

```
C#

IAsyncEnumerator<T> enumerator = enumerable.GetAsyncEnumerator();
try
{
    while (await enumerator.WaitForNextAsync())
    {
        while (true)
        {
            int item = enumerator.TryGetNext(out bool success);
            if (!success) break;
            Use(item);
        }
    }
}
finally { await enumerator.DisposeAsync(); }
```

The advantage of this is two-fold, one minor and one major:

- *Minor: Allows for an enumerator to support multiple consumers.* There may be scenarios where it's valuable for an enumerator to support multiple concurrent consumers. That can't be achieved when `MoveNextAsync` and `Current` are separate such that an implementation can't make their usage atomic. In contrast, this approach provides a single method `TryGetNext` that supports pushing the enumerator forward and getting the next item, so the enumerator can enable atomicity if desired. However, it's likely that such scenarios could also be enabled by giving each consumer its own enumerator from a shared enumerable. Further, we don't want to enforce that every enumerator support concurrent usage, as that would add non-trivial overheads to the majority case that doesn't require it, which means a consumer of the interface generally couldn't rely on this any way.
- *Major: Performance.* The `MoveNextAsync/Current` approach requires two interface calls per operation, whereas the best case for `WaitForNextAsync/TryGetNext` is that most iterations complete synchronously, enabling a tight inner loop with `TryGetNext`, such that we only have one interface call per operation. This can have

a measurable impact in situations where the interface calls dominate the computation.

However, there are non-trivial downsides, including significantly increased complexity when consuming these manually, and an increased chance of introducing bugs when using them. And while the performance benefits show up in microbenchmarks, we don't believe they'll be impactful in the vast majority of real usage. If it turns out they are, we can introduce a second set of interfaces in a light-up fashion.

Discarded options considered:

- `ValueTask<bool> WaitForNextAsync(); bool TryGetNext(out T result);`: `out` parameters can't be covariant. There's also a small impact here (an issue with the try pattern in general) that this likely incurs a runtime write barrier for reference type results.

Cancellation

There are several possible approaches to supporting cancellation:

1. `IAsyncEnumerable<T>/IAsyncEnumerator<T>` are cancellation-agnostic: `CancellationToken` doesn't appear anywhere. Cancellation is achieved by logically baking the `CancellationToken` into the enumerable and/or enumerator in whatever manner is appropriate, e.g. when calling an iterator, passing the `CancellationToken` as an argument to the iterator method and using it in the body of the iterator, as is done with any other parameter.
2. `IAsyncEnumerator<T>.GetAsyncEnumerator(CancellationToken)`: You pass a `CancellationToken` to `GetAsyncEnumerator`, and subsequent `MoveNextAsync` operations respect it however it can.
3. `IAsyncEnumerator<T>.MoveNextAsync(CancellationToken)`: You pass a `CancellationToken` to each individual `MoveNextAsync` call.
4. 1 && 2: You both embed `CancellationToken`s into your enumerable/enumerator and pass `CancellationToken`s into `GetAsyncEnumerator`.
5. 1 && 3: You both embed `CancellationToken`s into your enumerable/enumerator and pass `CancellationToken`s into `MoveNextAsync`.

From a purely theoretical perspective, (5) is the most robust, in that (a) `MoveNextAsync` accepting a `CancellationToken` enables the most fine-grained control over what's canceled, and (b) `CancellationToken` is just any other type that can be passed as an argument into iterators, embedded in arbitrary types, etc.

However, there are multiple problems with that approach:

- How does a `CancellationToken` passed to `GetAsyncEnumerator` make it into the body of the iterator? We could expose a new `iterator` keyword that you could dot off of to get access to the `CancellationToken` passed to `GetEnumerator`, but a) that's a lot of additional machinery, b) we're making it a very first-class citizen, and c) the 99% case would seem to be the same code both calling an iterator and calling `GetAsyncEnumerator` on it, in which case it can just pass the `CancellationToken` as an argument into the method.
- How does a `CancellationToken` passed to `MoveNextAsync` get into the body of the method? This is even worse, as if it's exposed off of an `iterator` local object, its value could change across awaits, which means any code that registered with the token would need to unregister from it prior to awaits and then re-register after; it's also potentially quite expensive to need to do such registering and unregistering in every `MoveNextAsync` call, regardless of whether implemented by the compiler in an iterator or by a developer manually.
- How does a developer cancel a `foreach` loop? If it's done by giving a `CancellationToken` to an enumerable/enumerator, then either a) we need to support `foreach`'ing over enumerators, which raises them to being first-class citizens, and now you need to start thinking about an ecosystem built up around enumerators (e.g. LINQ methods) or b) we need to embed the `CancellationToken` in the enumerable anyway by having some `WithCancellation` extension method off of `IAsyncEnumerable<T>` that would store the provided token and then pass it into the wrapped enumerable's `GetAsyncEnumerator` when the `GetAsyncEnumerator` on the returned struct is invoked (ignoring that token). Or, you can just use the `CancellationToken` you have in the body of the `foreach`.
- If/when query comprehensions are supported, how would the `CancellationToken` supplied to `GetEnumerator` or `MoveNextAsync` be passed into each clause? The easiest way would simply be for the clause to capture it, at which point whatever token is passed to `GetAsyncEnumerator`/`MoveNextAsync` is ignored.

An earlier version of this document recommended (1), but we since switched to (4).

The two main problems with (1):

- producers of cancellable enumerables have to implement some boilerplate, and can only leverage the compiler's support for async-iterators to implement a `IAsyncEnumerable<T> GetEnumerator(CancellationToken)` method.
- it is likely that many producers would be tempted to just add a `CancellationToken` parameter to their async-enumerable signature instead, which will prevent

consumers from passing the cancellation token they want when they are given an `IAsyncEnumerable` type.

There are two main consumption scenarios:

1. `await foreach (var i in GetData(token)) ...` where the consumer calls the async-iterator method,
2. `await foreach (var i in givenIAsyncEnumerable.WithCancellation(token)) ...` where the consumer deals with a given `IAsyncEnumerable` instance.

We find that a reasonable compromise to support both scenarios in a way that is convenient for both producers and consumers of async-streams is to use a specially annotated parameter in the async-iterator method. The `[EnumeratorCancellation]` attribute is used for this purpose. Placing this attribute on a parameter tells the compiler that if a token is passed to the `GetAsyncEnumerator` method, that token should be used instead of the value originally passed for the parameter.

Consider `IAsyncEnumerable<int> GetData([EnumeratorCancellation] CancellationToken token = default)`. The implementer of this method can simply use the parameter in the method body. The consumer can use either consumption patterns above:

1. if you use `GetData(token)`, then the token is saved into the async-enumerable and will be used in iteration,
2. if you use `givenIAsyncEnumerable.WithCancellation(token)`, then the token passed to `GetAsyncEnumerator` will supersede any token saved in the async-enumerable.

foreach

`foreach` will be augmented to support `IAsyncEnumerable<T>` in addition to its existing support for `IEnumerable<T>`. And it will support the equivalent of `IAsyncEnumerable<T>` as a pattern if the relevant members are exposed publicly, falling back to using the interface directly if not, in order to enable struct-based extensions that avoid allocating as well as using alternative awaitables as the return type of `MoveNextAsync` and `DisposeAsync`.

Syntax

Using the syntax:

```
C#
```

```
foreach (var i in enumerable)
```

C# will continue to treat `enumerable` as a synchronous enumerable, such that even if it exposes the relevant APIs for async enumerables (exposing the pattern or implementing the interface), it will only consider the synchronous APIs.

To force `foreach` to instead only consider the asynchronous APIs, `await` is inserted as follows:

```
C#  
  
await foreach (var i in enumerable)
```

No syntax would be provided that would support using either the async or the sync APIs; the developer must choose based on the syntax used.

Semantics

The compile-time processing of an `await foreach` statement first determines the **collection type**, **enumerator type** and **iteration type** of the expression (very similar to <https://github.com/dotnet/csharpstandard/blob/draft-v6/standard/statements.md#1295-the-foreach-statement>). This determination proceeds as follows:

- If the type `X` of *expression* is `dynamic` or an array type, then an error is produced and no further steps are taken.
- Otherwise, determine whether the type `X` has an appropriate `GetAsyncEnumerator` method:
 - Perform member lookup on the type `X` with identifier `GetAsyncEnumerator` and no type arguments. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match that is not a method group, check for an enumerable interface as described below.
 - Perform overload resolution using the resulting method group and an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, check for an enumerable interface as described below.
 - If the return type `E` of the `GetAsyncEnumerator` method is not a class, struct or interface type, an error is produced and no further steps are taken.
 - Member lookup is performed on `E` with the identifier `Current` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.

- Member lookup is performed on `E` with the identifier `MoveNextAsync` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.
- Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not awaitable into `bool`, an error is produced and no further steps are taken.
- The collection type is `X`, the enumerator type is `E`, and the iteration type is the type of the `Current` property.
- Otherwise, check for an enumerable interface:
 - If among all the types `Ti` for which there is an implicit conversion from `X` to `IAsyncEnumerable<Ti>`, there is a unique type `T` such that `T` is not dynamic and for all the other `Ti` there is an implicit conversion from `IAsyncEnumerable<T>` to `IAsyncEnumerable<Ti>`, then the collection type is the interface `IAsyncEnumerable<T>`, the enumerator type is the interface `IAsyncEnumerator<T>`, and the iteration type is `T`.
 - Otherwise, if there is more than one such type `T`, then an error is produced and no further steps are taken.
- Otherwise, an error is produced and no further steps are taken.

The above steps, if successful, unambiguously produce a collection type `C`, enumerator type `E` and iteration type `T`.

C#

```
await foreach (V v in x) «embedded_statement»
```

is then expanded to:

C#

```
{
    E e = ((C)(x)).GetAsyncEnumerator();
    try {
        while (await e.MoveNextAsync()) {
            V v = (V)(T)e.Current;
            «embedded_statement»
        }
    }
    finally {
        ... // Dispose e
    }
}
```

```
}  
}
```

The body of the `finally` block is constructed according to the following steps:

- If the type `E` has an appropriate `DisposeAsync` method:
 - Perform member lookup on the type `E` with identifier `DisposeAsync` and no type arguments. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match that is not a method group, check for the disposal interface as described below.
 - Perform overload resolution using the resulting method group and an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, check for the disposal interface as described below.
 - If the return type of the `DisposeAsync` method is not awaitable, an error is produced and no further steps are taken.
 - The `finally` clause is expanded to the semantic equivalent of:

C#

```
finally {  
    await e.DisposeAsync();  
}
```

- Otherwise, if there is an implicit conversion from `E` to the `System.IAsyncDisposable` interface, then
 - If `E` is a non-nullable value type then the `finally` clause is expanded to the semantic equivalent of:

C#

```
finally {  
    await ((System.IAsyncDisposable)e).DisposeAsync();  
}
```

- Otherwise the `finally` clause is expanded to the semantic equivalent of:

C#

```
finally {  
    System.IAsyncDisposable d = e as System.IAsyncDisposable;  
    if (d != null) await d.DisposeAsync();  
}
```

except that if `E` is a value type, or a type parameter instantiated to a value type, then the conversion of `e` to `System.IAsyncDisposable` shall not cause boxing to occur.

- Otherwise, the `finally` clause is expanded to an empty block:

```
C#  
  
finally {  
}
```

ConfigureAwait

This pattern-based compilation will allow `ConfigureAwait` to be used on all of the awaits, via a `ConfigureAwait` extension method:

```
C#  
  
await foreach (T item in enumerable.ConfigureAwait(false))  
{  
    ...  
}
```

This will be based on types we'll add to .NET as well, likely to `System.Threading.Tasks.Extensions.dll`:

```
C#  
  
// Approximate implementation, omitting arg validation and the like  
namespace System.Threading.Tasks  
{  
    public static class AsyncEnumerableExtensions  
    {  
        public static ConfiguredAsyncEnumerable<T> ConfigureAwait<T>(this  
IASyncEnumerable<T> enumerable, bool continueOnCapturedContext) =>  
            new ConfiguredAsyncEnumerable<T>(enumerable,  
continueOnCapturedContext);  
  
        public struct ConfiguredAsyncEnumerable<T>  
        {  
            private readonly IAsyncEnumerable<T> _enumerable;  
            private readonly bool _continueOnCapturedContext;  
  
            internal ConfiguredAsyncEnumerable(IAsyncEnumerable<T>  
enumerable, bool continueOnCapturedContext)  
            {  
                _enumerable = enumerable;  
                _continueOnCapturedContext = continueOnCapturedContext;  
            }  
        }  
    }  
}
```

```

    public ConfiguredAsyncEnumerator<T> GetAsyncEnumerator() =>
        new ConfiguredAsyncEnumerator<T>
            (_enumerable.GetAsyncEnumerator(), _continueOnCapturedContext);

    public struct ConfiguredAsyncEnumerator<T>
    {
        private readonly IAsyncEnumerator<T> _enumerator;
        private readonly bool _continueOnCapturedContext;

        internal Enumerator(IAsyncEnumerator<T> enumerator, bool
            continueOnCapturedContext)
        {
            _enumerator = enumerator;
            _continueOnCapturedContext = continueOnCapturedContext;
        }

        public ConfiguredValueTaskAwaitable<bool> MoveNextAsync() =>
            _enumerator.MoveNextAsync().ConfigureAwait(_continueOnCapturedContext);

        public T Current => _enumerator.Current;

        public ConfiguredValueTaskAwaitable DisposeAsync() =>
            _enumerator.DisposeAsync().ConfigureAwait(_continueOnCapturedContext);
    }
}

```

Note that this approach will not enable `ConfigureAwait` to be used with pattern-based enumerables, but then again it's already the case that the `ConfigureAwait` is only exposed as an extension on `Task/Task<T>/ValueTask/ValueTask<T>` and can't be applied to arbitrary awaitable things, as it only makes sense when applied to Tasks (it controls a behavior implemented in Task's continuation support), and thus doesn't make sense when using a pattern where the awaitable things may not be tasks. Anyone returning awaitable things can provide their own custom behavior in such advanced scenarios.

(If we can come up with some way to support a scope- or assembly-level `ConfigureAwait` solution, then this won't be necessary.)

Async Iterators

The language / compiler will support producing `IAsyncEnumerable<T>`s and `IAsyncEnumerator<T>`s in addition to consuming them. Today the language supports writing an iterator like:

C#

```
static IEnumerable<int> MyIterator()
{
    try
    {
        for (int i = 0; i < 100; i++)
        {
            Thread.Sleep(1000);
            yield return i;
        }
    }
    finally
    {
        Thread.Sleep(200);
        Console.WriteLine("finally");
    }
}
```

but `await` can't be used in the body of these iterators. We will add that support.

Syntax

The existing language support for iterators infers the iterator nature of the method based on whether it contains any `yields`. The same will be true for async iterators. Such async iterators will be demarcated and differentiated from synchronous iterators via adding `async` to the signature, and must then also have either `IAsyncEnumerable<T>` or `IAsyncEnumerator<T>` as its return type. For example, the above example could be written as an async iterator as follows:

C#

```
static async IAsyncEnumerable<int> MyIterator()
{
    try
    {
        for (int i = 0; i < 100; i++)
        {
            await Task.Delay(1000);
            yield return i;
        }
    }
    finally
    {
        await Task.Delay(200);
        Console.WriteLine("finally");
    }
}
```

Alternatives considered:

- *Not using `async` in the signature*: Using `async` is likely technically required by the compiler, as it uses it to determine whether `await` is valid in that context. But even if it's not required, we've established that `await` may only be used in methods marked as `async`, and it seems important to keep the consistency.
- *Enabling custom builders for `IAsyncEnumerable<T>`*: That's something we could look at for the future, but the machinery is complicated and we don't support that for the synchronous counterparts.
- *Having an `iterator` keyword in the signature*: Async iterators would use `async iterator` in the signature, and `yield` could only be used in `async` methods that included `iterator`; `iterator` would then be made optional on synchronous iterators. Depending on your perspective, this has the benefit of making it very clear by the signature of the method whether `yield` is allowed and whether the method is actually meant to return instances of type `IAsyncEnumerable<T>` rather than the compiler manufacturing one based on whether the code uses `yield` or not. But it is different from synchronous iterators, which don't and can't be made to require one. Plus some developers don't like the extra syntax. If we were designing it from scratch, we'd probably make this required, but at this point there's much more value in keeping async iterators close to sync iterators.

LINQ

There are over ~200 overloads of methods on the `System.Linq.Enumerable` class, all of which work in terms of `IEnumerable<T>`; some of these accept `IEnumerable<T>`, some of them produce `IEnumerable<T>`, and many do both. Adding LINQ support for `IAsyncEnumerable<T>` would likely entail duplicating all of these overloads for it, for another ~200. And since `IAsyncEnumerator<T>` is likely to be more common as a standalone entity in the asynchronous world than `IEnumerator<T>` is in the synchronous world, we could potentially need another ~200 overloads that work with `IAsyncEnumerator<T>`. Plus, a large number of the overloads deal with predicates (e.g. `Where` that takes a `Func<T, bool>`), and it may be desirable to have `IAsyncEnumerable<T>`-based overloads that deal with both synchronous and asynchronous predicates (e.g. `Func<T, ValueTask<bool>>` in addition to `Func<T, bool>`). While this isn't applicable to all of the now ~400 new overloads, a rough calculation is that it'd be applicable to half, which means another ~200 overloads, for a total of ~600 new methods.

That is a staggering number of APIs, with the potential for even more when extension libraries like Interactive Extensions (Ix) are considered. But Ix already has an implementation of many of these, and there doesn't seem to be a great reason to duplicate that work; we should instead help the community improve Ix and recommend it for when developers want to use LINQ with `IAsyncEnumerable<T>`.

There is also the issue of query comprehension syntax. The pattern-based nature of query comprehensions would allow them to "just work" with some operators, e.g. if Ix provides the following methods:

C#

```
public static IAsyncEnumerable<TResult> Select<TSource, TResult>(this
IAsyncEnumerable<TSource> source, Func<TSource, TResult> func);
public static IAsyncEnumerable<T> Where(this IAsyncEnumerable<T> source,
Func<T, bool> func);
```

then this C# code will "just work":

C#

```
IAsyncEnumerable<int> enumerable = ...;
IAsyncEnumerable<int> result = from item in enumerable
                               where item % 2 == 0
                               select item * 2;
```

However, there is no query comprehension syntax that supports using `await` in the clauses, so if Ix added, for example:

C#

```
public static IAsyncEnumerable<TResult> Select<TSource, TResult>(this
IAsyncEnumerable<TSource> source, Func<TSource, ValueTask<TResult>> func);
```

then this would "just work":

C#

```
IAsyncEnumerable<string> result = from url in urls
                                   where item % 2 == 0
                                   select SomeAsyncMethod(item);

async ValueTask<int> SomeAsyncMethod(int item)
{
    await Task.Yield();
    return item * 2;
}
```

but there'd be no way to write it with the `await` inline in the `select` clause. As a separate effort, we could look into adding `async { ... }` expressions to the language, at which point we could allow them to be used in query comprehensions and the above could instead be written as:

C#

```
IAsyncEnumerable<int> result = from item in enumerable
                               where item % 2 == 0
                               select async
                               {
                                   await Task.Yield();
                                   return item * 2;
                               };
```

or to enabling `await` to be used directly in expressions, such as by supporting `async from`. However, it's unlikely a design here would impact the rest of the feature set one way or the other, and this isn't a particularly high-value thing to invest in right now, so the proposal is to do nothing additional here right now.

Integration with other asynchronous frameworks

Integration with `IObservable<T>` and other asynchronous frameworks (e.g. reactive streams) would be done at the library level rather than at the language level. For example, all of the data from an `IAsyncEnumerator<T>` can be published to an `IObserver<T>` simply by `await foreach`'ing over the enumerator and `OnNext`'ing the data to the observer, so an `AsObservable<T>` extension method is possible. Consuming an `IObservable<T>` in a `await foreach` requires buffering the data (in case another item is pushed while the previous item is still being processing), but such a push-pull adapter can easily be implemented to enable an `IObservable<T>` to be pulled from with an `IAsyncEnumerator<T>`. Etc. Rx/lx already provide prototypes of such implementations, and libraries like <https://github.com/dotnet/corefx/tree/master/src/System.Threading.Channels> provide various kinds of buffering data structures. The language need not be involved at this stage.

Ranges

Article • 2021-11-09 • 12 minutes to read

Summary

This feature is about delivering two new operators that allow constructing `System.Index` and `System.Range` objects, and using them to index/slice collections at runtime.

Overview

Well-known types and members

To use the new syntactic forms for `System.Index` and `System.Range`, new well-known types and members may be necessary, depending on which syntactic forms are used.

To use the "hat" operator (`^`), the following is required

```
C#  
  
namespace System  
{  
    public readonly struct Index  
    {  
        public Index(int value, bool fromEnd);  
    }  
}
```

To use the `System.Index` type as an argument in an array element access, the following member is required:

```
C#  
  
int System.Index.GetOffset(int length);
```

The `..` syntax for `System.Range` will require the `System.Range` type, as well as one or more of the following members:

```
C#  
  
namespace System  
{  
    public readonly struct Range
```

```

    {
        public Range(System.Index start, System.Index end);
        public static Range StartAt(System.Index start);
        public static Range EndAt(System.Index end);
        public static Range All { get; }
    }
}

```

The `..` syntax allows for either, both, or none of its arguments to be absent. Regardless of the number of arguments, the `Range` constructor is always sufficient for using the `Range` syntax. However, if any of the other members are present and one or more of the `..` arguments are missing, the appropriate member may be substituted.

Finally, for a value of type `System.Range` to be used in an array element access expression, the following member must be present:

```

C#

namespace System.Runtime.CompilerServices
{
    public static class RuntimeHelpers
    {
        public static T[] GetSubArray<T>(T[] array, System.Range range);
    }
}

```

System.Index

C# has no way of indexing a collection from the end, but rather most indexers use the "from start" notion, or do a "length - i" expression. We introduce a new Index expression that means "from the end". The feature will introduce a new unary prefix "hat" operator. Its single operand must be convertible to `System.Int32`. It will be lowered into the appropriate `System.Index` factory method call.

We augment the grammar for *unary_expression* with the following additional syntax form:

```

antlr

unary_expression
    : '^' unary_expression
    ;

```

We call this the *index from end* operator. The predefined *index from end* operators are as follows:

```
C#
```

```
System.Index operator ^(int fromEnd);
```

The behavior of this operator is only defined for input values greater than or equal to zero.

Examples:

```
C#
```

```
var array = new int[] { 1, 2, 3, 4, 5 };  
var thirdItem = array[2]; // array[2]  
var lastItem = array[^1]; // array[new Index(1, fromEnd: true)]
```

System.Range

C# has no syntactic way to access "ranges" or "slices" of collections. Usually users are forced to implement complex structures to filter/operate on slices of memory, or resort to LINQ methods like `list.Skip(5).Take(2)`. With the addition of `System.Span<T>` and other similar types, it becomes more important to have this kind of operation supported on a deeper level in the language/runtime, and have the interface unified.

The language will introduce a new range operator `x..y`. It is a binary infix operator that accepts two expressions. Either operand can be omitted (examples below), and they have to be convertible to `System.Index`. It will be lowered to the appropriate `System.Range` factory method call.

We replace the C# grammar rules for *multiplicative_expression* with the following (in order to introduce a new precedence level):

```
antlr
```

```
range_expression  
  : unary_expression  
  | range_expression? '..' range_expression?  
  ;  
  
multiplicative_expression  
  : range_expression  
  | multiplicative_expression '*' range_expression  
  | multiplicative_expression '/' range_expression  
  | multiplicative_expression '%' range_expression  
  ;
```

All forms of the *range operator* have the same precedence. This new precedence group is lower than the *unary operators* and higher than the *multiplicative arithmetic operators*.

We call the `..` operator the *range operator*. The built-in range operator can roughly be understood to correspond to the invocation of a built-in operator of this form:

```
C#
```

```
System.Range operator ..(Index start = 0, Index end = ^0);
```

Examples:

```
C#
```

```
var array = new int[] { 1, 2, 3, 4, 5 };
var slice1 = array[2..^3]; // array[new Range(2, new Index(3, fromEnd:
true))]
var slice2 = array[..^3]; // array[Range.EndAt(new Index(3, fromEnd:
true))]
var slice3 = array[2..]; // array[Range.StartAt(2)]
var slice4 = array[..]; // array[Range.All]
```

Moreover, `System.Index` should have an implicit conversion from `System.Int32`, in order to avoid the need to overload mixing integers and indexes over multi-dimensional signatures.

Adding Index and Range support to existing library types

Implicit Index support

The language will provide an instance indexer member with a single parameter of type `Index` for types which meet the following criteria:

- The type is Countable.
- The type has an accessible instance indexer which takes a single `int` as the argument.
- The type does not have an accessible instance indexer which takes an `Index` as the first parameter. The `Index` must be the only parameter or the remaining parameters must be optional.

A type is **Countable** if it has a property named `Length` or `Count` with an accessible getter and a return type of `int`. The language can make use of this property to convert an expression of type `Index` into an `int` at the point of the expression without the need to use the type `Index` at all. In case both `Length` and `Count` are present, `Length` will be preferred. For simplicity going forward, the proposal will use the name `Length` to represent `Count` or `Length`.

For such types, the language will act as if there is an indexer member of the form `T this[Index index]` where `T` is the return type of the `int` based indexer including any `ref` style annotations. The new member will have the same `get` and `set` members with matching accessibility as the `int` indexer.

The new indexer will be implemented by converting the argument of type `Index` into an `int` and emitting a call to the `int` based indexer. For discussion purposes, let's use the example of `receiver[expr]`. The conversion of `expr` to `int` will occur as follows:

- When the argument is of the form `^expr2` and the type of `expr2` is `int`, it will be translated to `receiver.Length - expr2`.
- Otherwise, it will be translated as `expr.GetOffset(receiver.Length)`.

Regardless of the specific conversion strategy, the order of evaluation should be equivalent to the following:

1. `receiver` is evaluated;
2. `expr` is evaluated;
3. `length` is evaluated, if needed;
4. the `int` based indexer is invoked.

This allows for developers to use the `Index` feature on existing types without the need for modification. For example:

```
C#  
  
List<char> list = ...;  
var value = list[^1];  
  
// Gets translated to  
var value = list[list.Count - 1];
```

The `receiver` and `Length` expressions will be spilled as appropriate to ensure any side effects are only executed once. For example:

```
C#
```

```

class Collection {
    private int[] _array = new[] { 1, 2, 3 };

    public int Length {
        get {
            Console.WriteLine("Length ");
            return _array.Length;
        }
    }

    public int this[int index] => _array[index];
}

class SideEffect {
    Collection Get() {
        Console.WriteLine("Get ");
        return new Collection();
    }

    void Use() {
        int i = Get()[^1];
        Console.WriteLine(i);
    }
}

```

This code will print "Get Length 3".

Implicit Range support

The language will provide an instance indexer member with a single parameter of type `Range` for types which meet the following criteria:

- The type is Countable.
- The type has an accessible member named `Slice` which has two parameters of type `int`.
- The type does not have an instance indexer which takes a single `Range` as the first parameter. The `Range` must be the only parameter or the remaining parameters must be optional.

For such types, the language will bind as if there is an indexer member of the form `T this[Range range]` where `T` is the return type of the `Slice` method including any `ref` style annotations. The new member will also have matching accessibility with `Slice`.

When the `Range` based indexer is bound on an expression named `receiver`, it will be lowered by converting the `Range` expression into two values that are then passed to the `Slice` method. For discussion purposes, let's use the example of `receiver[expr]`.

The first argument of `Slice` will be obtained by converting the range typed expression in the following way:

- When `expr` is of the form `expr1..expr2` (where `expr2` can be omitted) and `expr1` has type `int`, then it will be emitted as `expr1`.
- When `expr` is of the form `^expr1..expr2` (where `expr2` can be omitted), then it will be emitted as `receiver.Length - expr1`.
- When `expr` is of the form `..expr2` (where `expr2` can be omitted), then it will be emitted as `0`.
- Otherwise, it will be emitted as `expr.Start.GetOffset(receiver.Length)`.

This value will be re-used in the calculation of the second `Slice` argument. When doing so it will be referred to as `start`. The second argument of `Slice` will be obtained by converting the range typed expression in the following way:

- When `expr` is of the form `expr1..expr2` (where `expr1` can be omitted) and `expr2` has type `int`, then it will be emitted as `expr2 - start`.
- When `expr` is of the form `expr1..^expr2` (where `expr1` can be omitted), then it will be emitted as `(receiver.Length - expr2) - start`.
- When `expr` is of the form `expr1..` (where `expr1` can be omitted), then it will be emitted as `receiver.Length - start`.
- Otherwise, it will be emitted as `expr.End.GetOffset(receiver.Length) - start`.

Regardless of the specific conversion strategy, the order of evaluation should be equivalent to the following:

1. `receiver` is evaluated;
2. `expr` is evaluated;
3. `length` is evaluated, if needed;
4. the `Slice` method is invoked.

The `receiver`, `expr`, and `length` expressions will be spilled as appropriate to ensure any side effects are only executed once. For example:

```
C#  
  
class Collection {  
    private int[] _array = new[] { 1, 2, 3 };  
  
    public int Length {  
        get {  
            Console.WriteLine("Length ");  
            return _array.Length;  
        }  
    }  
}
```

```

    }

    public int[] Slice(int start, int length) {
        var slice = new int[length];
        Array.Copy(_array, start, slice, 0, length);
        return slice;
    }
}

class SideEffect {
    Collection Get() {
        Console.Write("Get ");
        return new Collection();
    }

    void Use() {
        var array = Get()[0..2];
        Console.WriteLine(array.Length);
    }
}

```

This code will print "Get Length 2".

The language will special case the following known types:

- `string`: the method `Substring` will be used instead of `Slice`.
- `array`: the method `System.Runtime.CompilerServices.RuntimeHelpers.GetSubArray` will be used instead of `Slice`.

Alternatives

The new operators (`^` and `..`) are syntactic sugar. The functionality can be implemented by explicit calls to `System.Index` and `System.Range` factory methods, but it will result in a lot more boilerplate code, and the experience will be unintuitive.

IL Representation

These two operators will be lowered to regular indexer/method calls, with no change in subsequent compiler layers.

Runtime behavior

- Compiler can optimize indexers for built-in types like arrays and strings, and lower the indexing to the appropriate existing methods.
- `System.Index` will throw if constructed with a negative value.

- `^0` does not throw, but it translates to the length of the collection/enumerable it is supplied to.
- `Range.All` is semantically equivalent to `0..^0`, and can be deconstructed to these indices.

Considerations

Detect Indexable based on ICollection

The inspiration for this behavior was collection initializers. Using the structure of a type to convey that it had opted into a feature. In the case of collection initializers types can opt into the feature by implementing the interface `IEnumerable` (non generic).

This proposal initially required that types implement `ICollection` in order to qualify as Indexable. That required a number of special cases though:

- `ref struct`: these cannot implement interfaces yet types like `Span<T>` are ideal for index / range support.
- `string`: does not implement `ICollection` and adding that `interface` has a large cost.

This means to support key types special casing is already needed. The special casing of `string` is less interesting as the language does this in other areas (`foreach` lowering, constants, etc ...). The special casing of `ref struct` is more concerning as it's special casing an entire class of types. They get labeled as Indexable if they simply have a property named `Count` with a return type of `int`.

After consideration the design was normalized to say that any type which has a property `Count` / `Length` with a return type of `int` is Indexable. That removes all special casing, even for `string` and arrays.

Detect just Count

Detecting on the property names `Count` or `Length` does complicate the design a bit. Picking just one to standardize though is not sufficient as it ends up excluding a large number of types:

- Use `Length`: excludes pretty much every collection in `System.Collections` and sub-namespaces. Those tend to derive from `ICollection` and hence prefer `Count` over `length`.

- Use `Count`: excludes `string`, arrays, `Span<T>` and most `ref struct` based types

The extra complication on the initial detection of Indexable types is outweighed by its simplification in other aspects.

Choice of Slice as a name

The name `Slice` was chosen as it's the de-facto standard name for slice style operations in .NET. Starting with `netcoreapp2.1` all span style types use the name `Slice` for slicing operations. Prior to `netcoreapp2.1` there really aren't any examples of slicing to look to for an example. Types like `List<T>`, `ArraySegment<T>`, `SortedList<T>` would've been ideal for slicing but the concept didn't exist when types were added.

Thus, `Slice` being the sole example, it was chosen as the name.

Index target type conversion

Another way to view the `Index` transformation in an indexer expression is as a target type conversion. Instead of binding as if there is a member of the form `return_type this[Index]`, the language instead assigns a target typed conversion to `int`.

This concept could be generalized to all member access on Countable types. Whenever an expression with type `Index` is used as an argument to an instance member invocation and the receiver is Countable then the expression will have a target type conversion to `int`. The member invocations applicable for this conversion include methods, indexers, properties, extension methods, etc ... Only constructors are excluded as they have no receiver.

The target type conversion will be implemented as follows for any expression which has a type of `Index`. For discussion purposes lets use the example of `receiver[expr]`:

- When `expr` is of the form `^expr2` and the type of `expr2` is `int`, it will be translated to `receiver.Length - expr2`.
- Otherwise, it will be translated as `expr.GetOffset(receiver.Length)`.

The `receiver` and `Length` expressions will be spilled as appropriate to ensure any side effects are only executed once. For example:

```
C#  
  
class Collection {  
    private int[] _array = new[] { 1, 2, 3 };  
}
```

```

public int Length {
    get {
        Console.WriteLine("Length ");
        return _array.Length;
    }
}

public int GetAt(int index) => _array[index];
}

class SideEffect {
    Collection Get() {
        Console.WriteLine("Get ");
        return new Collection();
    }

    void Use() {
        int i = Get().GetAt(^1);
        Console.WriteLine(i);
    }
}

```

This code will print "Get Length 3".

This feature would be beneficial to any member which had a parameter that represented an index. For example `List<T>.InsertAt`. This also has the potential for confusion as the language can't give any guidance as to whether or not an expression is meant for indexing. All it can do is convert any `Index` expression to `int` when invoking a member on a Countable type.

Restrictions:

- This conversion is only applicable when the expression with type `Index` is directly an argument to the member. It would not apply to any nested expressions.

Decisions made during implementation

- All members in the pattern must be instance members
- If a Length method is found but it has the wrong return type, continue looking for Count
- The indexer used for the Index pattern must have exactly one int parameter
- The Slice method used for the Range pattern must have exactly two int parameters
- When looking for the pattern members, we look for original definitions, not constructed members

"pattern-based using" and "using declarations"

Article • 2022-12-14 • 3 minutes to read

Summary

The language will add two new capabilities around the `using` statement in order to make resource management simpler: `using` should recognize a disposable pattern in addition to `IDisposable` and add a `using` declaration to the language.

Motivation

The `using` statement is an effective tool for resource management today but it requires quite a bit of ceremony. Methods that have a number of resources to manage can get syntactically bogged down with a series of `using` statements. This syntax burden is enough that most coding style guidelines explicitly have an exception around braces for this scenario.

The `using` declaration removes much of the ceremony here and gets C# on par with other languages that include resource management blocks. Additionally the pattern-based `using` lets developers expand the set of types that can participate here. In many cases removing the need to create wrapper types that only exist to allow for a values use in a `using` statement.

Together these features allow developers to simplify and expand the scenarios where `using` can be applied.

Detailed Design

using declaration

The language will allow for `using` to be added to a local variable declaration. Such a declaration will have the same effect as declaring the variable in a `using` statement at the same location.

```

if (...)
{
    using FileStream f = new FileStream(@"C:\users\jaredpar\using.md");
    // statements
}

// Equivalent to
if (...)
{
    using (FileStream f = new FileStream(@"C:\users\jaredpar\using.md"))
    {
        // statements
    }
}

```

The lifetime of a `using` local will extend to the end of the scope in which it is declared. The `using` locals will then be disposed in the reverse order in which they are declared.

```

C#

{
    using var f1 = new FileStream("...");
    using var f2 = new FileStream("..."), f3 = new FileStream("...");
    ...
    // Dispose f3
    // Dispose f2
    // Dispose f1
}

```

There are no restrictions around `goto`, or any other control flow construct in the face of a `using` declaration. Instead the code acts just as it would for the equivalent `using` statement:

```

C#

{
    using var f1 = new FileStream("...");
target:
    using var f2 = new FileStream("...");
    if (someCondition)
    {
        // Causes f2 to be disposed but has no effect on f1
        goto target;
    }
}

```

A local declared in a `using` local declaration will be implicitly read-only. This matches the behavior of locals declared in a `using` statement.

The language grammar for `using` declarations will be the following:

```
antlr
```

```
local-using-declaration:  
    'using' type using-declarators  
  
using-declarators:  
    using-declarator  
    using-declarators , using-declarator  
  
using-declarator:  
    identifier = expression
```

Restrictions around `using` declaration:

- May not appear directly inside a `case` label but instead must be within a block inside the `case` label.
- May not appear as part of an `out` variable declaration.
- Must have an initializer for each declarator.
- The local type must be implicitly convertible to `IDisposable` or fulfill the `using` pattern.

pattern-based using

The language will add the notion of a disposable pattern for `ref struct` types: that is a `ref struct` which has an accessible `Dispose` instance method. Types which fit the disposable pattern can participate in a `using` statement or declaration without being required to implement `IDisposable`.

```
C#
```

```
ref struct Resource  
{  
    public void Dispose() { ... }  
}  
  
using (var r = new Resource())  
{  
    // statements  
}
```

This will allow developers to leverage `using` for `ref struct` types. These types can't implement interfaces today and hence can't participate in `using` statements.

The same restrictions from a traditional `using` statement apply here as well: local variables declared in the `using` are read-only, a `null` value will not cause an exception to be thrown, etc ... The code generation will be different only in that there will not be a cast to `IDisposable` before calling `Dispose`:

```
C#  
  
{  
    Resource r = new Resource();  
    try {  
        // statements  
    }  
    finally {  
        if (r != null) r.Dispose();  
    }  
}
```

In order to fit the disposable pattern the `Dispose` method must be an accessible instance member, parameterless and have a `void` return type. It cannot be an extension method.

Considerations

case labels without blocks

A `using declaration` is illegal directly inside a `case` label due to complications around its actual lifetime. One potential solution is to simply give it the same lifetime as an `out var` in the same location. It was deemed the extra complexity to the feature implementation and the ease of the work around (just add a block to the `case` label) didn't justify taking this route.

Future Expansions

fixed locals

A `fixed` statement has all of the properties of `using` statements that motivated the ability to have `using` locals. Consideration should be given to extending this feature to `fixed` locals as well. The lifetime and ordering rules should apply equally well for `using` and `fixed` here.

Static local functions

Article • 2021-09-21 • 2 minutes to read

Summary

Support local functions that disallow capturing state from the enclosing scope.

Motivation

Avoid unintentionally capturing state from the enclosing context. Allow local functions to be used in scenarios where a `static` method is required.

Detailed design

A local function declared `static` cannot capture state from the enclosing scope. As a result, locals, parameters, and `this` from the enclosing scope are not available within a `static` local function.

A `static` local function cannot reference instance members from an implicit or explicit `this` or `base` reference.

A `static` local function may reference `static` members from the enclosing scope.

A `static` local function may reference `constant` definitions from the enclosing scope.

`nameof()` in a `static` local function may reference locals, parameters, or `this` or `base` from the enclosing scope.

Accessibility rules for `private` members in the enclosing scope are the same for `static` and non-`static` local functions.

A `static` local function definition is emitted as a `static` method in metadata, even if only used in a delegate.

A non-`static` local function or lambda can capture state from an enclosing `static` local function but cannot capture state outside the enclosing `static` local function.

A `static` local function cannot be invoked in an expression tree.

A call to a local function is emitted as `call` rather than `callvirt`, regardless of whether the local function is `static`.

Overload resolution of a call within a local function not affected by whether the local function is `static`.

Removing the `static` modifier from a local function in a valid program does not change the meaning of the program.

Null coalescing assignment

Article • 2022-06-14 • 2 minutes to read

Summary

Simplifies a common coding pattern where a variable is assigned a value if it is null.

As part of this proposal, we will also loosen the type requirements on `??` to allow an expression whose type is an unconstrained type parameter to be used on the left-hand side.

Motivation

It is common to see code of the form

```
C#  
  
if (variable == null)  
{  
    variable = expression;  
}
```

This proposal adds a non-overloadable binary operator to the language that performs this function.

There have been at least eight separate community requests for this feature.

Detailed design

We add a new form of assignment operator

```
antlr  
  
assignment_operator  
    : '??='  
    ;
```

Which follows the existing semantic rules for compound assignment operators ([§11.18.3](#)), except that we elide the assignment if the left-hand side is non-null. The rules for this feature are as follows.

Given `a ??= b`, where `A` is the type of `a`, `B` is the type of `b`, and `A0` is the underlying type of `A` if `A` is a nullable value type:

1. If `A` does not exist or is a non-nullable value type, a compile-time error occurs.
2. If `B` is not implicitly convertible to `A` or `A0` (if `A0` exists), a compile-time error occurs.
3. If `A0` exists and `B` is implicitly convertible to `A0`, and `B` is not dynamic, then the type of `a ??= b` is `A0`. `a ??= b` is evaluated at runtime as:

```
C#  
  
var tmp = a.GetValueOrDefault();  
if (!a.HasValue) { tmp = b; a = tmp; }  
tmp
```

Except that `a` is only evaluated once.

4. Otherwise, the type of `a ??= b` is `A`. `a ??= b` is evaluated at runtime as `a ?? (a = b)`, except that `a` is only evaluated once.

For the relaxation of the type requirements of `??`, we update the spec where it currently states that, given `a ?? b`, where `A` is the type of `a`:

1. If `A` exists and is not a nullable type or a reference type, a compile-time error occurs.

We relax this requirement to:

1. If `A` exists and is a non-nullable value type, a compile-time error occurs.

This allows the null coalescing operator to work on unconstrained type parameters, as the unconstrained type parameter `T` exists, is not a nullable type, and is not a reference type.

Drawbacks

As with any language feature, we must question whether the additional complexity to the language is repaid in the additional clarity offered to the body of C# programs that would benefit from the feature.

Alternatives

The programmer can write `(x = x ?? y)`, `if (x == null) x = y;`, or `x ?? (x = y)` by hand.

Unresolved questions

- Requires LDM review
- Should we also support `&&=` and `||=` operators?

Design meetings

None.

ReadOnly Instance Members

Article • 2021-09-21 • 4 minutes to read

Championed Issue: <https://github.com/dotnet/csharplang/issues/1710> ↗

Summary

Provide a way to specify individual instance members on a struct do not modify state, in the same way that `readonly struct` specifies no instance members modify state.

It is worth noting that `readonly instance member` \neq `pure instance member`. A `pure` instance member guarantees no state will be modified. A `readonly` instance member only guarantees that instance state will not be modified.

All instance members on a `readonly struct` could be considered implicitly `readonly instance members`. Explicit `readonly instance members` declared on non-readonly structs would behave in the same manner. For example, they would still create hidden copies if you called an instance member (on the current instance or on a field of the instance) which was itself not-readonly.

Motivation

Today, users have the ability to create `readonly struct` types which the compiler enforces that all fields are readonly (and by extension, that no instance members modify the state). However, there are some scenarios where you have an existing API that exposes accessible fields or that has a mix of mutating and non-mutating members. Under these circumstances, you cannot mark the type as `readonly` (it would be a breaking change).

This normally doesn't have much impact, except in the case of `in` parameters. With `in` parameters for non-readonly structs, the compiler will make a copy of the parameter for each instance member invocation, since it cannot guarantee that the invocation does not modify internal state. This can lead to a multitude of copies and worse overall performance than if you had just passed the struct directly by value. For an example, see this code on [sharplab](#) ↗

Some other scenarios where hidden copies can occur include `static readonly fields` and `literals`. If they are supported in the future, `blittable constants` would end up in

the same boat; that is they all currently necessitate a full copy (on instance member invocation) if the struct is not marked `readonly`.

Design

Allow a user to specify that an instance member is, itself, `readonly` and does not modify the state of the instance (with all the appropriate verification done by the compiler, of course). For example:

C#

```
public struct Vector2
{
    public float x;
    public float y;

    public readonly float GetLengthReadOnly()
    {
        return MathF.Sqrt(LengthSquared);
    }

    public float GetLength()
    {
        return MathF.Sqrt(LengthSquared);
    }

    public readonly float GetLengthIllegal()
    {
        var tmp = MathF.Sqrt(LengthSquared);

        x = tmp;    // Compiler error, cannot write x
        y = tmp;    // Compiler error, cannot write y

        return tmp;
    }

    public readonly float LengthSquared
    {
        get
        {
            return (x * x) +
                   (y * y);
        }
    }
}

public static class MyClass
{
    public static float ExistingBehavior(in Vector2 vector)
    {
        // This code causes a hidden copy, the compiler effectively emits:
```

```

    //    var tmpVector = vector;
    //    return tmpVector.GetLength();
    //
    // This is done because the compiler doesn't know that `GetLength()`
    // won't mutate `vector`.

    return vector.GetLength();
}

public static float ReadonlyBehavior(in Vector2 vector)
{
    // This code is emitted exactly as listed. There are no hidden
    // copies as the `readonly` modifier indicates that the method
    // won't mutate `vector`.

    return vector.GetLengthReadonly();
}
}

```

Readonly can be applied to property accessors to indicate that `this` will not be mutated in the accessor. The following examples have readonly setters because those accessors modify the state of member field, but do not modify the value of that member field.

C#

```

public readonly int Prop1
{
    get
    {
        return this._store["Prop1"];
    }
    set
    {
        this._store["Prop1"] = value;
    }
}

```

When `readonly` is applied to the property syntax, it means that all accessors are `readonly`.

C#

```

public readonly int Prop2
{
    get
    {
        return this._store["Prop2"];
    }
    set
    {

```

```
        this._store["Prop2"] = value;
    }
}
```

ReadOnly can only be applied to accessors which do not mutate the containing type.

```
C#

public int Prop3
{
    readonly get
    {
        return this._prop3;
    }
    set
    {
        this._prop3 = value;
    }
}
```

ReadOnly can be applied to some auto-implemented properties, but it won't have a meaningful effect. The compiler will treat all auto-implemented getters as readonly whether or not the `readonly` keyword is present.

```
C#

// Allowed
public readonly int Prop4 { get; }
public int Prop5 { readonly get; }
public int Prop6 { readonly get; set; }

// Not allowed
public readonly int Prop7 { get; set; }
public int Prop8 { get; readonly set; }
```

ReadOnly can be applied to manually-implemented events, but not field-like events. ReadOnly cannot be applied to individual event accessors (add/remove).

```
C#

// Allowed
public readonly event Action<EventArgs> Event1
{
    add { }
    remove { }
}

// Not allowed
public readonly event Action<EventArgs> Event2;
```

```

public event Action<EventArgs> Event3
{
    readonly add { }
    readonly remove { }
}
public static readonly event Event4
{
    add { }
    remove { }
}

```

Some other syntax examples:

- Expression bodied members: `public readonly float ExpressionBodiedMember => (x * x) + (y * y);`
- Generic constraints: `public readonly void GenericMethod<T>(T value) where T : struct { }`

The compiler would emit the instance member, as usual, and would additionally emit a compiler recognized attribute indicating that the instance member does not modify state. This effectively causes the hidden `this` parameter to become `in T` instead of `ref T`.

This would allow the user to safely call said instance method without the compiler needing to make a copy.

The restrictions would include:

- The `readonly` modifier cannot be applied to static methods, constructors or destructors.
- The `readonly` modifier cannot be applied to delegates.
- The `readonly` modifier cannot be applied to members of class or interface.

Drawbacks

Same drawbacks as exist with `readonly struct` methods today. Certain code may still cause hidden copies.

Notes

Using an attribute or another keyword may also be possible.

This proposal is somewhat related to (but is more a subset of) `functional purity` and/or `constant expressions`, both of which have had some existing proposals.

Permit `stackalloc` in nested contexts

Article • 2022-02-23 • 2 minutes to read

Stack allocation

We modify the section *Stack allocation* (§22.9) of the C# language specification to relax the places when a `stackalloc` expression may appear. We delete

```
antlr
```

```
local_variable_initializer_unsafe
    : stackalloc_initializer
    ;

stackalloc_initializer
    : 'stackalloc' unmanaged_type '[' expression ']'
    ;
```

and replace them with

```
antlr
```

```
primary_no_array_creation_expression
    : stackalloc_initializer
    ;

stackalloc_initializer
    : 'stackalloc' unmanaged_type '[' expression? ']' array_initializer?
    | 'stackalloc' '[' expression? ']' array_initializer
    ;
```

Note that the addition of an *array_initializer* to *stackalloc_initializer* (and making the index expression optional) was an [extension in C# 7.3](#) and is not described here.

The *element type* of the `stackalloc` expression is the *unmanaged_type* named in the `stackalloc` expression, if any, or the common type among the elements of the *array_initializer* otherwise.

The type of the *stackalloc_initializer* with *element type* `K` depends on its syntactic context:

- If the *stackalloc_initializer* appears directly as the *local_variable_initializer* of a *local_variable_declaration* statement or a *for_initializer*, then its type is `K*`.
- Otherwise its type is `System.Span<K>`.

Stackalloc Conversion

The *stackalloc conversion* is a new built-in implicit conversion from expression. When the type of a *stackalloc_initializer* is `K*`, there is an implicit *stackalloc conversion* from the *stackalloc_initializer* to the type `System.Span<K>`.

Records

Article • 2021-09-21 • 14 minutes to read

This proposal tracks the specification for the C# 9 records feature, as agreed to by the C# language design team.

The syntax for a record is as follows:

antlr

```
record_declaration
    : attributes? class_modifier* 'partial'? 'record' identifier
    type_parameter_list?
      parameter_list? record_base? type_parameter_constraints_clause*
    record_body
    ;

record_base
    : ':' class_type argument_list?
    | ':' interface_type_list
    | ':' class_type argument_list? ',' interface_type_list
    ;

record_body
    : '{' class_member_declaration* '}' ';'
    | ';'
    ;
```

Record types are reference types, similar to a class declaration. It is an error for a record to provide a `record_base` `argument_list` if the `record_declaration` does not contain a `parameter_list`. At most one partial type declaration of a partial record may provide a `parameter_list`.

Record parameters cannot use `ref`, `out` or `this` modifiers (but `in` and `params` are allowed).

Inheritance

Records cannot inherit from classes, unless the class is `object`, and classes cannot inherit from records. Records can inherit from other records.

Members of a record type

In addition to the members declared in the record body, a record type has additional synthesized members. Members are synthesized unless a member with a "matching" signature is declared in the record body or an accessible concrete non-virtual member with a "matching" signature is inherited. A matching member prevents the compiler from generating that member, not any other synthesized members. Two members are considered matching if they have the same signature or would be considered "hiding" in an inheritance scenario. It is an error for a member of a record to be named "Clone". It is an error for an instance field of a record to have an unsafe type.

The synthesized members are as follows:

Equality members

If the record is derived from `object`, the record type includes a synthesized readonly property equivalent to a property declared as follows:

```
C#  
  
Type EqualityContract { get; };
```

The property is `private` if the record type is `sealed`. Otherwise, the property is `virtual` and `protected`. The property can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`.

If the record type is derived from a base record type `Base`, the record type includes a synthesized readonly property equivalent to a property declared as follows:

```
C#  
  
protected override Type EqualityContract { get; };
```

The property can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`. It is an error if either synthesized, or explicitly declared property doesn't override a property with this signature in the record type `Base` (for example, if the property is missing in the `Base`, or sealed, or not virtual, etc.). The synthesized property returns `typeof(R)` where `R` is the record type.

The record type implements `System.IEquatable<R>` and includes a synthesized strongly-typed overload of `Equals(R? other)` where `R` is the record type. The method is `public`, and the method is `virtual` unless the record type is `sealed`. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`.

If `Equals(R? other)` is user-defined (not synthesized) but `GetHashCode` is not, a warning is produced.

```
C#
```

```
public virtual bool Equals(R? other);
```

The synthesized `Equals(R?)` returns `true` if and only if each of the following are `true`:

- `other` is not `null`, and
- For each instance field `fieldN` in the record type that is not inherited, the value of `System.Collections.Generic.EqualityComparer<TN>.Default.Equals(fieldN, other.fieldN)` where `TN` is the field type, and
- If there is a base record type, the value of `base.Equals(other)` (a non-virtual call to `public virtual bool Equals(Base? other)`); otherwise the value of `EqualityContract == other.EqualityContract`.

The record type includes synthesized `==` and `!=` operators equivalent to operators declared as follows:

```
C#
```

```
public static bool operator==(R? left, R? right)
    => (object)left == right || (left?.Equals(right) ?? false);
public static bool operator!=(R? left, R? right)
    => !(left == right);
```

The `Equals` method called by the `==` operator is the `Equals(R? other)` method specified above. The `!=` operator delegates to the `==` operator. It is an error if the operators are declared explicitly.

If the record type is derived from a base record type `Base`, the record type includes a synthesized override equivalent to a method declared as follows:

```
C#
```

```
public sealed override bool Equals(Base? other);
```

It is an error if the override is declared explicitly. It is an error if the method doesn't override a method with same signature in record type `Base` (for example, if the method is missing in the `Base`, or sealed, or not virtual, etc.). The synthesized override returns `Equals((object?)other)`.

The record type includes a synthesized override equivalent to a method declared as follows:

```
C#
```

```
public override bool Equals(object? obj);
```

It is an error if the override is declared explicitly. It is an error if the method doesn't override `object.Equals(object? obj)` (for example, due to shadowing in intermediate base types, etc.). The synthesized override returns `Equals(other as R)` where `R` is the record type.

The record type includes a synthesized override equivalent to a method declared as follows:

```
C#
```

```
public override int GetHashCode();
```

The method can be declared explicitly. It is an error if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`. It is an error if either synthesized, or explicitly declared method doesn't override `object.GetHashCode()` (for example, due to shadowing in intermediate base types, etc.).

A warning is reported if one of `Equals(R?)` and `GetHashCode()` is explicitly declared but the other method is not explicit.

The synthesized override of `GetHashCode()` returns an `int` result of combining the following values:

- For each instance field `fieldN` in the record type that is not inherited, the value of `System.Collections.Generic.EqualityComparer<TN>.Default.GetHashCode(fieldN)` where `TN` is the field type, and
- If there is a base record type, the value of `base.GetHashCode()`; otherwise the value of

```
System.Collections.Generic.EqualityComparer<System.Type>.Default.GetHashCode(EqualityContract).
```

For example, consider the following record types:

```
C#  
  
record R1(T1 P1);  
record R2(T1 P1, T2 P2) : R1(P1);  
record R3(T1 P1, T2 P2, T3 P3) : R2(P1, P2);
```

For those record types, the synthesized equality members would be something like:

```
C#  
  
class R1 : IEquatable<R1>  
{  
    public T1 P1 { get; init; }  
    protected virtual Type EqualityContract => typeof(R1);  
    public override bool Equals(object? obj) => Equals(obj as R1);  
    public virtual bool Equals(R1? other)  
    {  
        return !(other is null) &&  
            EqualityContract == other.EqualityContract &&  
            EqualityComparer<T1>.Default.Equals(P1, other.P1);  
    }  
    public static bool operator==(R1? left, R1? right)  
        => (object)left == right || (left?.Equals(right) ?? false);  
    public static bool operator!=(R1? left, R1? right)  
        => !(left == right);  
    public override int GetHashCode()  
    {  
        return  
Combine(EqualityComparer<Type>.Default.GetHashCode(EqualityContract),  
        EqualityComparer<T1>.Default.GetHashCode(P1));  
    }  
}  
  
class R2 : R1, IEquatable<R2>  
{  
    public T2 P2 { get; init; }  
    protected override Type EqualityContract => typeof(R2);  
    public override bool Equals(object? obj) => Equals(obj as R2);  
    public sealed override bool Equals(R1? other) => Equals((object?)other);  
    public virtual bool Equals(R2? other)  
    {  
        return base.Equals((R1?)other) &&  
            EqualityComparer<T2>.Default.Equals(P2, other.P2);  
    }  
    public static bool operator==(R2? left, R2? right)  
        => (object)left == right || (left?.Equals(right) ?? false);  
    public static bool operator!=(R2? left, R2? right)
```

```

=> !(left == right);
public override int GetHashCode()
{
    return Combine(base.GetHashCode(),
        EqualityComparer<T2>.Default.GetHashCode(P2));
}
}

class R3 : R2, IEquatable<R3>
{
    public T3 P3 { get; init; }
    protected override Type EqualityContract => typeof(R3);
    public override bool Equals(object? obj) => Equals(obj as R3);
    public sealed override bool Equals(R2? other) => Equals((object?)other);
    public virtual bool Equals(R3? other)
    {
        return base.Equals((R2?)other) &&
            EqualityComparer<T3>.Default.Equals(P3, other.P3);
    }
    public static bool operator==(R3? left, R3? right)
        => (object)left == right || (left?.Equals(right) ?? false);
    public static bool operator!=(R3? left, R3? right)
        => !(left == right);
    public override int GetHashCode()
    {
        return Combine(base.GetHashCode(),
            EqualityComparer<T3>.Default.GetHashCode(P3));
    }
}

```

Copy and Clone members

A record type contains two copying members:

- A constructor taking a single argument of the record type. It is referred to as a "copy constructor".
- A synthesized public parameterless instance "clone" method with a compiler-reserved name

The purpose of the copy constructor is to copy the state from the parameter to the new instance being created. This constructor doesn't run any instance field/property initializers present in the record declaration. If the constructor is not explicitly declared, a constructor will be synthesized by the compiler. If the record is sealed, the constructor will be private, otherwise it will be protected. An explicitly declared copy constructor must be either public or protected, unless the record is sealed. The first thing the constructor must do, is to call a copy constructor of the base, or a parameter-less object constructor if the record inherits from object. An error is reported if a user-defined copy constructor uses an implicit or explicit constructor initializer that doesn't fulfill this

requirement. After a base copy constructor is invoked, a synthesized copy constructor copies values for all instance fields implicitly or explicitly declared within the record type. The sole presence of a copy constructor, whether explicit or implicit, doesn't prevent an automatic addition of a default instance constructor.

If a virtual "clone" method is present in the base record, the synthesized "clone" method overrides it and the return type of the method is the current containing type if the "covariant returns" feature is supported and the override return type otherwise. An error is produced if the base record clone method is sealed. If a virtual "clone" method is not present in the base record, the return type of the clone method is the containing type and the method is virtual, unless the record is sealed or abstract. If the containing record is abstract, the synthesized clone method is also abstract. If the "clone" method is not abstract, it returns the result of a call to a copy constructor.

Printing members: PrintMembers and ToString methods

If the record is derived from `object`, the record includes a synthesized method equivalent to a method declared as follows:

```
C#
```

```
bool PrintMembers(System.Text.StringBuilder builder);
```

The method is `private` if the record type is `sealed`. Otherwise, the method is `virtual` and `protected`.

The method:

1. calls the method

```
System.Runtime.CompilerServices.RuntimeHelpers.EnsureSufficientExecutionStack  
( ) if the method is present and the record has printable members.
```

2. for each of the record's printable members (non-static public field and readable property members), appends that member's name followed by " = " followed by the member's value separated with ", ",
3. return true if the record has printable members.

For a member that has a value type, we will convert its value to a string representation using the most efficient method available to the target platform. At present that means calling `ToString` before passing to `StringBuilder.Append`.

If the record type is derived from a base record `Base`, the record includes a synthesized override equivalent to a method declared as follows:

```
C#
```

```
protected override bool PrintMembers(StringBuilder builder);
```

If the record has no printable members, the method calls the base `PrintMembers` method with one argument (its `builder` parameter) and returns the result.

Otherwise, the method:

1. calls the base `PrintMembers` method with one argument (its `builder` parameter),
2. if the `PrintMembers` method returned true, append ", " to the builder,
3. for each of the record's printable members, appends that member's name followed by " = " followed by the member's value: `this.member` (or `this.member.ToString()` for value types), separated with ", ",
4. return true.

The `PrintMembers` method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`.

The record includes a synthesized method equivalent to a method declared as follows:

```
C#
```

```
public override string ToString();
```

The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`. It is an error if either synthesized, or explicitly declared method doesn't override `object.ToString()` (for example, due to shadowing in intermediate base types, etc.).

The synthesized method:

1. creates a `StringBuilder` instance,
2. appends the record name to the builder, followed by " { ",
3. invokes the record's `PrintMembers` method giving it the builder, followed by " " if it returned true,
4. appends "}",
5. returns the builder's contents with `builder.ToString()`.

For example, consider the following record types:

C#

```
record R1(T1 P1);  
record R2(T1 P1, T2 P2, T3 P3) : R1(P1);
```

For those record types, the synthesized printing members would be something like:

C#

```
class R1 : IEquatable<R1>  
{  
    public T1 P1 { get; init; }  
  
    protected virtual bool PrintMembers(StringBuilder builder)  
    {  
        builder.Append(nameof(P1));  
        builder.Append(" = ");  
        builder.Append(this.P1); // or builder.Append(this.P1.ToString());  
        if P1 has a value type  
  
        return true;  
    }  
  
    public override string ToString()  
    {  
        var builder = new StringBuilder();  
        builder.Append(nameof(R1));  
        builder.Append(" { ");  
  
        if (PrintMembers(builder))  
            builder.Append(" ");  
  
        builder.Append("}");  
        return builder.ToString();  
    }  
}  
  
class R2 : R1, IEquatable<R2>  
{  
    public T2 P2 { get; init; }  
    public T3 P3 { get; init; }  
  
    protected override bool PrintMembers(StringBuilder builder)  
    {  
        if (base.PrintMembers(builder))  
            builder.Append(", ");  
  
        builder.Append(nameof(P2));  
        builder.Append(" = ");  
        builder.Append(this.P2); // or builder.Append(this.P2); if P2 has a  
        value type  
  
        builder.Append(", ");  
    }  
}
```

```

        builder.Append(nameof(P3));
        builder.Append(" = ");
        builder.Append(this.P3); // or builder.Append(this.P3); if P3 has a
value type

        return true;
    }

    public override string ToString()
    {
        var builder = new StringBuilder();
        builder.Append(nameof(R2));
        builder.Append(" { ");

        if (PrintMembers(builder))
            builder.Append(" ");

        builder.Append("}");
        return builder.ToString();
    }
}

```

Positional record members

In addition to the above members, records with a parameter list ("positional records") synthesize additional members with the same conditions as the members above.

Primary Constructor

A record type has a public constructor whose signature corresponds to the value parameters of the type declaration. This is called the primary constructor for the type, and causes the implicitly declared default class constructor, if present, to be suppressed. It is an error to have a primary constructor and a constructor with the same signature already present in the class.

At runtime the primary constructor

1. executes the instance initializers appearing in the class-body
2. invokes the base class constructor with the arguments provided in the `record_base` clause, if present

If a record has a primary constructor, any user-defined constructor, except "copy constructor" must have an explicit `this` constructor initializer.

Parameters of the primary constructor as well as members of the record are in scope within the `argument_list` of the `record_base` clause and within initializers of instance fields or properties. Instance members would be an error in these locations (similar to how instance members are in scope in regular constructor initializers today, but an error to use), but the parameters of the primary constructor would be in scope and useable and would shadow members. Static members would also be useable, similar to how base calls and initializers work in ordinary constructors today.

A warning is produced if a parameter of the primary constructor is not read.

Expression variables declared in the `argument_list` are in scope within the `argument_list`. The same shadowing rules as within an argument list of a regular constructor initializer apply.

Properties

For each record parameter of a record type declaration there is a corresponding public property member whose name and type are taken from the value parameter declaration.

For a record:

- A public `get` and `init` auto-property is created (see separate `init` accessor specification). An inherited `abstract` property with matching type is overridden. It is an error if the inherited property does not have `public` overridable `get` and `init` accessors. It is an error if the inherited property is hidden.

The auto-property is initialized to the value of the corresponding primary constructor parameter. Attributes can be applied to the synthesized auto-property and its backing field by using `property:` or `field:` targets for attributes syntactically applied to the corresponding record parameter.

Deconstruct

A positional record with at least one parameter synthesizes a public void-returning instance method called `Deconstruct` with an out parameter declaration for each parameter of the primary constructor declaration. Each parameter of the `Deconstruct` method has the same type as the corresponding parameter of the primary constructor declaration. The body of the method assigns each parameter of the `Deconstruct` method to the value from an instance member access to a member of the same name. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or is static.

with expression

A `with` expression is a new expression using the following syntax.

```
antlr
```

```
with_expression
: switch_expression
| switch_expression 'with' '{' member_initializer_list? '}'
;

member_initializer_list
: member_initializer (',' member_initializer)*
;

member_initializer
: identifier '=' expression
;
```

A `with` expression is not permitted as a statement.

A `with` expression allows for "non-destructive mutation", designed to produce a copy of the receiver expression with modifications in assignments in the `member_initializer_list`.

A valid `with` expression has a receiver with a non-void type. The receiver type must be a record.

On the right hand side of the `with` expression is a `member_initializer_list` with a sequence of assignments to *identifier*, which must be an accessible instance field or property of the receiver's type.

First, receiver's "clone" method (specified above) is invoked and its result is converted to the receiver's type. Then, each `member_initializer` is processed the same way as an assignment to a field or property access of the result of the conversion. Assignments are processed in lexical order.

Top-level statements

Article • 2022-06-23 • 4 minutes to read

Summary

Allow a sequence of *statements* to occur right before the *namespace_member_declarations* of a *compilation_unit* (i.e. source file).

The semantics are that if such a sequence of *statements* is present, the following type declaration, modulo the actual method name, would be emitted:

```
c#  
  
partial class Program  
{  
    static async Task Main(string[] args)  
    {  
        // statements  
    }  
}
```

See also <https://github.com/dotnet/csharplang/issues/3117> .

Motivation

There's a certain amount of boilerplate surrounding even the simplest of programs, because of the need for an explicit `Main` method. This seems to get in the way of language learning and program clarity. The primary goal of the feature therefore is to allow `C#` programs without unnecessary boilerplate around them, for the sake of learners and the clarity of code.

Detailed design

Syntax

The only additional syntax is allowing a sequence of *statements* in a compilation unit, just before the *namespace_member_declarations*:

```
antlr
```

```
compilation_unit
    : extern_alias_directive* using_directive* global_attributes? statement*
  namespace_member_declaration*
    ;
```

Only one *compilation_unit* is allowed to have *statements*.

Example:

```
c#

if (args.Length == 0
    || !int.TryParse(args[0], out int n)
    || n < 0) return;
Console.WriteLine(Fib(n).curr);

(int curr, int prev) Fib(int i)
{
    if (i == 0) return (1, 0);
    var (curr, prev) = Fib(i - 1);
    return (curr + prev, curr);
}
```

Semantics

If any top-level statements are present in any compilation unit of the program, the meaning is as if they were combined in the block body of a `Main` method of a `Program` class in the global namespace, as follows:

```
c#

partial class Program
{
    static async Task Main(string[] args)
    {
        // statements
    }
}
```

The type is named "Program", so can be referenced by name from source code. It is a partial type, so a type named "Program" in source code must also be declared as partial. But the method name "Main" is used only for illustration purposes, the actual name used by the compiler is implementation dependent and the method cannot be referenced by name from source code.

The method is designated as the entry point of the program. Explicitly declared methods that by convention could be considered as an entry point candidates are ignored. A warning is reported when that happens. It is an error to specify `-main:<type>` compiler switch when there are top-level statements.

The entry point method always has one formal parameter, `string[] args`. The execution environment creates and passes a `string[]` argument containing the command-line arguments that were specified when the application was started. The `string[]` argument is never null, but it may have a length of zero if no command-line arguments were specified. The 'args' parameter is in scope within top-level statements and is not in scope outside of them. Regular name conflict/shadowing rules apply.

Async operations are allowed in top-level statements to the degree they are allowed in statements within a regular async entry point method. However, they are not required, if `await` expressions and other async operations are omitted, no warning is produced.

The signature of the generated entry point method is determined based on operations used by the top level statements as follows:

Async-operations\Return-with-expression	Present	Absent
Present	<code>static Task<int> Main(string[] args)</code>	<code>static Task Main(string[] args)</code>
Absent	<code>static int Main(string[] args)</code>	<code>static void Main(string[] args)</code>

The example above would yield the following `$Main` method declaration:

```
c#
partial class Program
{
    static void $Main(string[] args)
    {
        if (args.Length == 0
            || !int.TryParse(args[0], out int n)
            || n < 0) return;
        Console.WriteLine(Fib(n).curr);

        (int curr, int prev) Fib(int i)
        {
            if (i == 0) return (1, 0);
            var (curr, prev) = Fib(i - 1);
            return (curr + prev, curr);
        }
    }
}
```

```
}  
}
```

At the same time an example like this:

```
c#
```

```
await System.Threading.Tasks.Task.Delay(1000);  
System.Console.WriteLine("Hi!");
```

would yield:

```
c#
```

```
partial class Program  
{  
    static async Task $Main(string[] args)  
    {  
        await System.Threading.Tasks.Task.Delay(1000);  
        System.Console.WriteLine("Hi!");  
    }  
}
```

An example like this:

```
c#
```

```
await System.Threading.Tasks.Task.Delay(1000);  
System.Console.WriteLine("Hi!");  
return 0;
```

would yield:

```
c#
```

```
partial class Program  
{  
    static async Task<int> $Main(string[] args)  
    {  
        await System.Threading.Tasks.Task.Delay(1000);  
        System.Console.WriteLine("Hi!");  
        return 0;  
    }  
}
```

And an example like this:

```
c#
```

```
System.Console.WriteLine("Hi!");  
return 2;
```

would yield:

```
c#
```

```
partial class Program  
{  
    static int $Main(string[] args)  
    {  
        System.Console.WriteLine("Hi!");  
        return 2;  
    }  
}
```

Scope of top-level local variables and local functions

Even though top-level local variables and functions are "wrapped" into the generated entry point method, they should still be in scope throughout the program in every compilation unit. For the purpose of simple-name evaluation, once the global namespace is reached:

- First, an attempt is made to evaluate the name within the generated entry point method and only if this attempt fails
- The "regular" evaluation within the global namespace declaration is performed.

This could lead to name shadowing of namespaces and types declared within the global namespace as well as to shadowing of imported names.

If the simple name evaluation occurs outside of the top-level statements and the evaluation yields a top-level local variable or function, that should lead to an error.

In this way we protect our future ability to better address "Top-level functions" (scenario 2 in <https://github.com/dotnet/csharplang/issues/3117>), and are able to give useful diagnostics to users who mistakenly believe them to be supported.

Nullable Reference Types Specification

Article • 2021-10-20 • 18 minutes to read

This is a work in progress - several parts are missing or incomplete.

This feature adds two new kinds of nullable types (nullable reference types and nullable generic types) to the existing nullable value types, and introduces a static flow analysis for purpose of null-safety.

Syntax

Nullable reference types and nullable type parameters

Nullable reference types and nullable type parameters have the same syntax `T?` as the short form of nullable value types, but do not have a corresponding long form.

For the purposes of the specification, the current `nullable_type` production is renamed to `nullable_value_type`, and `nullable_reference_type` and `nullable_type_parameter` productions are added:

```
antlr
```

```
type
```

```
: value_type  
| reference_type  
| nullable_type_parameter  
| type_parameter  
| type_unsafe  
;
```

```
reference_type
```

```
: ...  
| nullable_reference_type  
;
```

```
nullable_reference_type
```

```
: non_nullable_reference_type '?'  
;
```

```
non_nullable_reference_type
```

```
: reference_type  
;
```

```
nullable_type_parameter
```

```
: non_nullable_non_value_type_parameter '?'  
;
```

```
non_nullable_non_value_type_parameter
    : type_parameter
    ;
```

The `non_nullable_reference_type` in a `nullable_reference_type` must be a nonnullable reference type (class, interface, delegate or array).

The `non_nullable_non_value_type_parameter` in `nullable_type_parameter` must be a type parameter that isn't constrained to be a value type.

Nullable reference types and nullable type parameters cannot occur in the following positions:

- as a base class or interface
- as the receiver of a `member_access`
- as the `type` in an `object_creation_expression`
- as the `delegate_type` in a `delegate_creation_expression`
- as the `type` in an `is_expression`, a `catch_clause` or a `type_pattern`
- as the `interface` in a fully qualified interface member name

A warning is given on a `nullable_reference_type` and `nullable_type_parameter` in a *disabled* nullable annotation context.

class and class? constraint

The `class` constraint has a nullable counterpart `class?`:

```
antlr

primary_constraint
    : ...
    | 'class' '?'
    ;
```

A type parameter constrained with `class` (in an *enabled* annotation context) must be instantiated with a nonnullable reference type.

A type parameter constrained with `class?` (or `class` in a *disabled* annotation context) may either be instantiated with a nullable or nonnullable reference type.

A warning is given on a `class?` constraint in a *disabled* annotation context.

nonnull constraint

A type parameter constrained with `nonnull` may not be a nullable type (nullable value type, nullable reference type or nullable type parameter).

antlr

```
primary_constraint
: ...
| 'nonnull'
;
```

default constraint

The `default` constraint can be used on a method override or explicit implementation to disambiguate `T?` meaning "nullable type parameter" from "nullable value type" (`Nullable<T>`). Lacking the `default` constraint a `T?` syntax in an override or explicit implementation will be interpreted as `Nullable<T>`

See <https://github.com/dotnet/csharplang/blob/master/proposals/csharp-9.0/unconstrained-type-parameter-annotations.md#default-constraint>

The null-forgiving operator

The post-fix `!` operator is called the null-forgiving operator. It can be applied on a *primary_expression* or within a *null_conditional_expression*:

antlr

```
primary_expression
: ...
| null_forgiving_expression
;

null_forgiving_expression
: primary_expression '!'
;

null_conditional_expression
: primary_expression null_conditional_operations_no_suppression
suppression?
;

null_conditional_operations_no_suppression
: null_conditional_operations? '?' '.' identifier type_argument_list?
| null_conditional_operations? '?' '[' argument_list ']'
```

```

| null_conditional_operations '.' identifier type_argument_list?
| null_conditional_operations '[' argument_list ']'
| null_conditional_operations '(' argument_list? ')'
;

null_conditional_operations
: null_conditional_operations_no_suppression suppression?
;

suppression
: '!'
;

```

For example:

C#

```

var v = expr!;
expr!.M();
_ = a?.b!.c;

```

The postfix `!` operator has no runtime effect - it evaluates to the result of the underlying expression. Its only role is to change the null state of the expression to "not null", and to limit warnings given on its use.

Nullable compiler directives

`#nullable` directives control the nullable annotation and warning contexts.

antlr

```

pp_directive
: ...
| pp_nullable
;

pp_nullable
: whitespace? '#' whitespace? 'nullable' whitespace nullable_action
(whitespace nullable_target)? pp_new_line
;

nullable_action
: 'disable'
| 'enable'
| 'restore'
;

nullable_target
: 'warnings'

```

```
| 'annotations'  
;
```

`#pragma warning` directives are expanded to allow changing the nullable warning context:

```
antlr
```

```
pragma_warning_body  
: ...  
| 'warning' whitespace warning_action whitespace 'nullable'  
;
```

For example:

```
C#
```

```
#pragma warning disable nullable
```

Nullable contexts

Every line of source code has a *nullable annotation context* and a *nullable warning context*. These control whether nullable annotations have effect, and whether nullability warnings are given. The annotation context of a given line is either *disabled* or *enabled*. The warning context of a given line is either *disabled* or *enabled*.

Both contexts can be specified at the project level (outside of C# source code), or anywhere within a source file via `#nullable` pre-processor directives. If no project level settings are provided the default is for both contexts to be *disabled*.

The `#nullable` directive controls the annotation and warning contexts within the source text, and take precedence over the project-level settings.

A directive sets the context(s) it controls for subsequent lines of code, until another directive overrides it, or until the end of the source file.

The effect of the directives is as follows:

- `#nullable disable`: Sets the nullable annotation and warning contexts to *disabled*
- `#nullable enable`: Sets the nullable annotation and warning contexts to *enabled*
- `#nullable restore`: Restores the nullable annotation and warning contexts to project settings
- `#nullable disable annotations`: Sets the nullable annotation context to *disabled*

- `#nullable enable annotations`: Sets the nullable annotation context to *enabled*
- `#nullable restore annotations`: Restores the nullable annotation context to project settings
- `#nullable disable warnings`: Sets the nullable warning context to *disabled*
- `#nullable enable warnings`: Sets the nullable warning context to *enabled*
- `#nullable restore warnings`: Restores the nullable warning context to project settings

Nullability of types

A given type can have one of three nullabilities: *oblivious*, *nonnullable*, and *nullable*.

Nonnullable types may cause warnings if a potential `null` value is assigned to them. *Oblivious* and *nullable* types, however, are "null-assignable" and can have `null` values assigned to them without warnings.

Values of *oblivious* and *nonnullable* types can be dereferenced or assigned without warnings. Values of *nullable* types, however, are "null-yielding" and may cause warnings when dereferenced or assigned without proper null checking.

The *default null state* of a null-yielding type is "maybe null" or "maybe default". The default null state of a non-null-yielding type is "not null".

The kind of type and the nullable annotation context it occurs in determine its nullability:

- A nonnullable value type `S` is always *nonnullable*
- A nullable value type `S?` is always *nullable*
- An unannotated reference type `C` in a *disabled* annotation context is *oblivious*
- An unannotated reference type `C` in an *enabled* annotation context is *nonnullable*
- A nullable reference type `C?` is *nullable* (but a warning may be yielded in a *disabled* annotation context)

Type parameters additionally take their constraints into account:

- A type parameter `T` where all constraints (if any) are either nullable types or the `class?` constraint is *nullable*
- A type parameter `T` where at least one constraint is either *oblivious* or *nonnullable* or one of the `struct` or `class` or `notnull` constraints is
 - *oblivious* in a *disabled* annotation context
 - *nonnullable* in an *enabled* annotation context

- A nullable type parameter `T?` is *nullable*, but a warning is yielded in a *disabled* annotation context if `T` isn't a value type

Oblivious vs nonnullable

A `type` is deemed to occur in a given annotation context when the last token of the type is within that context.

Whether a given reference type `C` in source code is interpreted as oblivious or nonnullable depends on the annotation context of that source code. But once established, it is considered part of that type, and "travels with it" e.g. during substitution of generic type arguments. It is as if there is an annotation like `?` on the type, but invisible.

Constraints

Nullable reference types can be used as generic constraints.

`class?` is a new constraint denoting "possibly nullable reference type", whereas `class` in an *enabled* annotation context denotes "nonnullable reference type".

`default` is a new constraint denoting a type parameter that isn't known to be a reference or value type. It can only be used on overridden and explicitly implemented methods. With this constraint, `T?` means a nullable type parameter, as opposed to being a shorthand for `Nullable<T>`.

`notnull` is a new constraint denoting a type parameter that is nonnullable.

The nullability of a type argument or of a constraint does not impact whether the type satisfies the constraint, except where that is already the case today (nullable value types do not satisfy the `struct` constraint). However, if the type argument does not satisfy the nullability requirements of the constraint, a warning may be given.

Null state and null tracking

Every expression in a given source location has a *null state*, which indicated whether it is believed to potentially evaluate to null. The null state is either "not null", "maybe null", or "maybe default". The null state is used to determine whether a warning should be given about null-unsafe conversions and dereferences.

The distinction between "maybe null" and "maybe default" is subtle and applies to type parameters. The distinction is that a type parameter `T` which has the state "maybe null" means the value is in the domain of legal values for `T` however that legal value may include `null`. Whereas a "maybe default" means that the value may be outside the legal domain of values for `T`.

Example:

```
c#
```

```
// The value `t` here has the state "maybe null". It's possible for `T` to
// be instantiated
// with `string?` in which case `null` would be within the domain of legal
// values here. The
// assumption though is the value provided here is within the legal values
// of `T`. Hence
// if `T` is `string` then `null` will not be a value, just as we assume
// that `null` is not
// provided for a normal `string` parameter
void M<T>(T t)
{
    // There is no guarantee that default(T) is within the legal values for
    // T hence the
    // state *must* be "maybe-default" and hence `local` must be `T?`
    T? local = default(T);
}
```

Null tracking for variables

For certain expressions denoting variables, fields or properties, the null state is tracked between occurrences, based on assignments to them, tests performed on them and the control flow between them. This is similar to how definite assignment is tracked for variables. The tracked expressions are the ones of the following form:

```
antlr
```

```
tracked_expression
    : simple_name
    | this
    | base
    | tracked_expression '.' identifier
    ;
```

Where the identifiers denote fields or properties.

The null state for tracked variables is "not null" in unreachable code. This follows other decisions around unreachable code like considering all locals to be definitely assigned.

Describe null state transitions similar to definite assignment

Null state for expressions

The null state of an expression is derived from its form and type, and from the null state of variables involved in it.

Literals

The null state of a `null` literal depends on the target type of the expression. If the target type is a type parameter constrained to a reference type then it's "maybe default". Otherwise it is "maybe null".

The null state of a `default` literal depends on the target type of the `default` literal. A `default` literal with target type `T` has the same null state as the `default(T)` expression.

The null state of any other literal is "not null".

Simple names

If a `simple_name` is not classified as a value, its null state is "not null". Otherwise it is a tracked expression, and its null state is its tracked null state at this source location.

Member access

If a `member_access` is not classified as a value, its null state is "not null". Otherwise, if it is a tracked expression, its null state is its tracked null state at this source location. Otherwise its null state is the default null state of its type.

```
c#
```

```
var person = new Person();

// The receiver is a tracked expression hence the member_access of the
// property
// is tracked as well
if (person.FirstName is not null)
{
    Use(person.FirstName);
}

// The return of an invocation is not a tracked expression hence the
// member_access
// of the return is also not tracked
if (GetAnonymous().FirstName is not null)
```

```

{
    // Warning: Cannot convert null literal to non-nullable reference type.
    Use(GetAnonymous().FirstName);
}

void Use(string s)
{
    // ...
}

public class Person
{
    public string? FirstName { get; set; }
    public string? LastName { get; set; }

    private static Person s_anonymous = new Person();
    public static Person GetAnonymous() => s_anonymous;
}

```

Invocation expressions

If an `invocation_expression` invokes a member that is declared with one or more attributes for special null behavior, the null state is determined by those attributes. Otherwise the null state of the expression is the default null state of its type.

The null state of an `invocation_expression` is not tracked by the compiler.

```

c#

// The result of an invocation_expression is not tracked
if (GetText() is not null)
{
    // Warning: Converting null literal or possible null value to non-
    nullable type.
    string s = GetText();
    // Warning: Dereference of a possibly null reference.
    Use(s);
}

// Nullable friendly pattern
if (GetText() is string s)
{
    Use(s);
}

string? GetText() => ...
Use(string s) { }

```

Element access

If an `element_access` invokes an indexer that is declared with one or more attributes for special null behavior, the null state is determined by those attributes. Otherwise the null state of the expression is the default null state of its type.

```
c#
```

```
object?[] array = ...;
if (array[0] != null)
{
    // Warning: Converting null literal or possible null value to non-
    // nullable type.
    object o = array[0];
    // Warning: Dereference of a possibly null reference.
    Console.WriteLine(o.ToString());
}

// Nullable friendly pattern
if (array[0] is {} o)
{
    Console.WriteLine(o.ToString());
}
```

Base access

If `B` denotes the base type of the enclosing type, `base.I` has the same null state as `((B)this).I` and `base[E]` has the same null state as `((B)this)[E]`.

Default expressions

`default(T)` has the null state based on the properties of the type `T`:

- If the type is a *nonnullable* type then it has the null state "not null"
- Else if the type is a type parameter then it has the null state "maybe default"
- Else it has the null state "maybe null"

Null-conditional expressions ?.

A `null_conditional_expression` has the null state based on the expression type. Note that this refers to the type of the `null_conditional_expression`, not the original type of the member being invoked:

- If the type is a *nullable* value type then it has the null state "maybe null"

- Else if the type is a *nullable* type parameter then it has the null state "maybe default"
- Else it has the null state "maybe null"

Cast expressions

If a cast expression `(T)E` invokes a user-defined conversion, then the null state of the expression is the default null state for the type of the user-defined conversion.

Otherwise:

- If `T` is a *nonnullable* value type then `T` has the null state "not null"
- Else if `T` is a *nullable* value type then `T` has the null state "maybe null"
- Else if `T` is a *nullable* type in the form `U?` where `U` is a type parameter then `T` has the null state "maybe default"
- Else if `T` is a *nullable* type, and `E` has null state "maybe null" or "maybe default", then `T` has the null state "maybe null"
- Else if `T` is a type parameter, and `E` has null state "maybe null" or "maybe default", then `T` has the null state "maybe default"
- Else `T` has the same null state as `E`

Unary and binary operators

If a unary or binary operator invokes an user-defined operator then the null state of the expression is the default null state for the type of the user-defined operator. Otherwise it is the null state of the expression.

Something special to do for binary `+` over strings and delegates?

Await expressions

The null state of `await E` is the default null state of its type.

The `as` operator

The null state of an `E as T` expression depends first on properties of the type `T`. If the type of `T` is *nonnullable* then the null state is "not null". Otherwise the null state depends on the conversion from the type of `E` to type `T`:

- If the conversion is an identity, boxing, implicit reference, or implicit nullable conversion, then the null state is the null state of `E`

- Else if `T` is a type parameter then it has the null state "maybe default"
- Else it has the null state "maybe null"

The null-coalescing operator

The null state of `E1 ?? E2` is the null state of `E2`

The conditional operator

The null state of `E1 ? E2 : E3` is based on the null state of `E2` and `E3`:

- If both are "not null" then the null state is "not null"
- Else if either is "maybe default" then the null state is "maybe default"
- Else the null state is "not null"

Query expressions

The null state of a query expression is the default null state of its type.

Additional work needed here

Assignment operators

`E1 = E2` and `E1 op= E2` have the same null state as `E2` after any implicit conversions have been applied.

Expressions that propagate null state

`(E)`, `checked(E)` and `unchecked(E)` all have the same null state as `E`.

Expressions that are never null

The null state of the following expression forms is always "not null":

- `this` access
- interpolated strings
- `new` expressions (object, delegate, anonymous object and array creation expressions)
- `typeof` expressions
- `nameof` expressions

- anonymous functions (anonymous methods and lambda expressions)
- null-forgiving expressions
- `is` expressions

Nested functions

Nested functions (lambdas and local functions) are treated like methods, except in regards to their captured variables. The initial state of a captured variable inside a lambda or local function is the intersection of the nullable state of the variable at all the "uses" of that nested function or lambda. A use of a local function is either a call to that function, or where it is converted to a delegate. A use of a lambda is the point at which it is defined in source.

Type inference

nullable implicitly typed local variables

`var` infers an annotated type for reference types, and type parameters that aren't constrained to be a value type. For instance:

- in `var s = ""`; the `var` is inferred as `string?`.
- in `var t = new T()`; with an unconstrained `T` the `var` is inferred as `T?`.

Generic type inference

Generic type inference is enhanced to help decide whether inferred reference types should be nullable or not. This is a best effort. It may yield warnings regarding nullability constraints, and may lead to nullable warnings when the inferred types of the selected overload are applied to the arguments.

The first phase

Nullable reference types flow into the bounds from the initial expressions, as described below. In addition, two new kinds of bounds, namely `null` and `default` are introduced. Their purpose is to carry through occurrences of `null` or `default` in the input expressions, which may cause an inferred type to be nullable, even when it otherwise wouldn't.

The determination of what bounds to add in the first phase are enhanced as follows:

If an argument `Ei` has a reference type, the type `U` used for inference depends on the null state of `Ei` as well as its declared type:

- If the declared type is a nonnullable reference type `U0` or a nullable reference type `U0?` then
 - if the null state of `Ei` is "not null" then `U` is `U0`
 - if the null state of `Ei` is "maybe null" then `U` is `U0?`
- Otherwise if `Ei` has a declared type, `U` is that type
- Otherwise if `Ei` is `null` then `U` is the special bound `null`
- Otherwise if `Ei` is `default` then `U` is the special bound `default`
- Otherwise no inference is made.

Exact, upper-bound and lower-bound inferences

In inferences *from* the type `U` *to* the type `V`, if `V` is a nullable reference type `V0?`, then `V0` is used instead of `V` in the following clauses.

- If `V` is one of the unfixed type variables, `U` is added as an exact, upper or lower bound as before
- Otherwise, if `U` is `null` or `default`, no inference is made
- Otherwise, if `U` is a nullable reference type `U0?`, then `U0` is used instead of `U` in the subsequent clauses.

The essence is that nullability that pertains directly to one of the unfixed type variables is preserved into its bounds. For the inferences that recurse further into the source and target types, on the other hand, nullability is ignored. It may or may not match, but if it doesn't, a warning will be issued later if the overload is chosen and applied.

Fixing

The spec currently does not do a good job of describing what happens when multiple bounds are identity convertible to each other, but are different. This may happen between `object` and `dynamic`, between tuple types that differ only in element names, between types constructed thereof and now also between `C` and `C?` for reference types.

In addition we need to propagate "nullness" from the input expressions to the result type.

To handle these we add more phases to fixing, which is now:

1. Gather all the types in all the bounds as candidates, removing `?` from all that are nullable reference types
2. Eliminate candidates based on requirements of exact, lower and upper bounds (keeping `null` and `default` bounds)
3. Eliminate candidates that do not have an implicit conversion to all the other candidates
4. If the remaining candidates do not all have identity conversions to one another, then type inference fails
5. *Merge* the remaining candidates as described below
6. If the resulting candidate is a reference type and *all* of the exact bounds or *any* of the lower bounds are nullable reference types, `null` or `default`, then `?` is added to the resulting candidate, making it a nullable reference type.

Merging is described between two candidate types. It is transitive and commutative, so the candidates can be merged in any order with the same ultimate result. It is undefined if the two candidate types are not identity convertible to each other.

The *Merge* function takes two candidate types and a direction (+ or -):

- $Merge(T, T, d) = T$
- $Merge(S, T?, +) = Merge(S?, T, +) = Merge(S, T, +)?$
- $Merge(S, T?, -) = Merge(S?, T, -) = Merge(S, T, -)$
- $Merge(C<S_1, \dots, S_n>, C<T_1, \dots, T_n>, +) = C<Merge(S_1, T_1, d_1), \dots, Merge(S_n, T_n, d_n)>$, where
 - $d_i = +$ if the i 'th type parameter of $C<\dots>$ is covariant
 - $d_i = -$ if the i 'th type parameter of $C<\dots>$ is contra- or invariant
- $Merge(C<S_1, \dots, S_n>, C<T_1, \dots, T_n>, -) = C<Merge(S_1, T_1, d_1), \dots, Merge(S_n, T_n, d_n)>$, where
 - $d_i = -$ if the i 'th type parameter of $C<\dots>$ is covariant
 - $d_i = +$ if the i 'th type parameter of $C<\dots>$ is contra- or invariant
- $Merge((S_1\ s_1, \dots, S_n\ s_n), (T_1\ t_1, \dots, T_n\ t_n), d) = (Merge(S_1, T_1, d)_{n_1}, \dots, Merge(S_n, T_n, d)_{n_n})$, where
 - n_i is absent if s_i and t_i differ, or if both are absent
 - n_i is s_i if s_i and t_i are the same
- $Merge(object, dynamic) = Merge(dynamic, object) = dynamic$

Warnings

Potential null assignment

Potential null dereference

Pattern-matching changes for C# 9.0

Article • 2021-09-21 • 11 minutes to read

We are considering a small handful of enhancements to pattern-matching for C# 9.0 that have natural synergy and work well to address a number of common programming problems:

- <https://github.com/dotnet/csharplang/issues/2925> Type patterns
- <https://github.com/dotnet/csharplang/issues/1350> Parenthesized patterns to enforce or emphasize precedence of the new combinators
- <https://github.com/dotnet/csharplang/issues/1350> Conjunctive `and` patterns that require both of two different patterns to match;
- <https://github.com/dotnet/csharplang/issues/1350> Disjunctive `or` patterns that require either of two different patterns to match;
- <https://github.com/dotnet/csharplang/issues/1350> Negated `not` patterns that require a given pattern *not* to match; and
- <https://github.com/dotnet/csharplang/issues/812> Relational patterns that require the input value to be less than, less than or equal to, etc a given constant.

Parenthesized Patterns

Parenthesized patterns permit the programmer to put parentheses around any pattern. This is not so useful with the existing patterns in C# 8.0, however the new pattern combinators introduce a precedence that the programmer may want to override.

```
antlr
```

```
primary_pattern
    : parenthesized_pattern
    | // all of the existing forms
    ;
parenthesized_pattern
    : '(' pattern ')'
```

Type Patterns

We permit a type as a pattern:

```
antlr
```

```

primary_pattern
  : type-pattern
  | // all of the existing forms
  ;
type_pattern
  : type
  ;

```

This retcons the existing *is-type-expression* to be an *is-pattern-expression* in which the pattern is a *type-pattern*, though we would not change the syntax tree produced by the compiler.

One subtle implementation issue is that this grammar is ambiguous. A string such as `a.b` can be parsed either as a qualified name (in a type context) or a dotted expression (in an expression context). The compiler is already capable of treating a qualified name the same as a dotted expression in order to handle something like `e is Color.Red`. The compiler's semantic analysis would be further extended to be capable of binding a (syntactic) constant pattern (e.g. a dotted expression) as a type in order to treat it as a bound type pattern in order to support this construct.

After this change, you would be able to write

```

C#

void M(object o1, object o2)
{
    var t = (o1, o2);
    if (t is (int, string)) {} // test if o1 is an int and o2 is a string
    switch (o1) {
        case int: break; // test if o1 is an int
        case System.String: break; // test if o1 is a string
    }
}

```

Relational Patterns

Relational patterns permit the programmer to express that an input value must satisfy a relational constraint when compared to a constant value:

```

C#

public static LifeStage LifeStageAtAge(int age) => age switch
{
    < 0 => LifeStage.Prenatal,
    < 2 => LifeStage.Infant,
    < 4 => LifeStage.Toddler,

```

```

    < 6 => LifeStage.EarlyChild,
    < 12 => LifeStage.MiddleChild,
    < 20 => LifeStage.Adolescent,
    < 40 => LifeStage.EarlyAdult,
    < 65 => LifeStage.MiddleAdult,
    _ => LifeStage.LateAdult,
};

```

Relational patterns support the relational operators `<`, `<=`, `>`, and `>=` on all of the built-in types that support such binary relational operators with two operands of the same type in an expression. Specifically, we support all of these relational patterns for `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `nint`, and `nuint`.

antlr

```

primary_pattern
    : relational_pattern
    ;
relational_pattern
    : '<' relational_expression
    | '<=' relational_expression
    | '>' relational_expression
    | '>=' relational_expression
    ;

```

The expression is required to evaluate to a constant value. It is an error if that constant value is `double.NaN` or `float.NaN`. It is an error if the expression is a null constant.

When the input is a type for which a suitable built-in binary relational operator is defined that is applicable with the input as its left operand and the given constant as its right operand, the evaluation of that operator is taken as the meaning of the relational pattern. Otherwise we convert the input to the type of the expression using an explicit nullable or unboxing conversion. It is a compile-time error if no such conversion exists. The pattern is considered not to match if the conversion fails. If the conversion succeeds then the result of the pattern-matching operation is the result of evaluating the expression `e OP v` where `e` is the converted input, `OP` is the relational operator, and `v` is the constant expression.

Pattern Combinators

Pattern *combinators* permit matching both of two different patterns using `and` (this can be extended to any number of patterns by the repeated use of `and`), either of two different patterns using `or` (ditto), or the *negation* of a pattern using `not`.

A common use of a combinator will be the idiom

```
c#  
  
if (e is not null) ...
```

More readable than the current idiom `e is object`, this pattern clearly expresses that one is checking for a non-null value.

The `and` and `or` combinators will be useful for testing ranges of values

```
c#  
  
bool IsLetter(char c) => c is >= 'a' and <= 'z' or >= 'A' and <= 'Z';
```

This example illustrates that `and` will have a higher parsing priority (i.e. will bind more closely) than `or`. The programmer can use the *parenthesized pattern* to make the precedence explicit:

```
c#  
  
bool IsLetter(char c) => c is (>= 'a' and <= 'z') or (>= 'A' and <= 'Z');
```

Like all patterns, these combinators can be used in any context in which a pattern is expected, including nested patterns, the *is-pattern-expression*, the *switch-expression*, and the pattern of a switch statement's case label.

```
antlr  
  
pattern  
    : disjunctive_pattern  
    ;  
disjunctive_pattern  
    : disjunctive_pattern 'or' conjunctive_pattern  
    | conjunctive_pattern  
    ;  
conjunctive_pattern  
    : conjunctive_pattern 'and' negated_pattern  
    | negated_pattern  
    ;  
negated_pattern  
    : 'not' negated_pattern  
    | primary_pattern  
    ;  
primary_pattern  
    : // all of the patterns forms previously defined  
    ;
```

Change to 7.5.4.2 Grammar Ambiguities

Due to the introduction of the *type pattern*, it is possible for a generic type to appear before the token `=>`. We therefore add `=>` to the set of tokens listed in *7.5.4.2 Grammar Ambiguities* to permit disambiguation of the `<` that begins the type argument list. See also <https://github.com/dotnet/roslyn/issues/47614>.

Open Issues with Proposed Changes

Syntax for relational operators

Are `and`, `or`, and `not` some kind of contextual keyword? If so, is there a breaking change (e.g. compared to their use as a designator in a *declaration-pattern*).

Semantics (e.g. type) for relational operators

We expect to support all of the primitive types that can be compared in an expression using a relational operator. The meaning in simple cases is clear

```
c#
```

```
bool IsValidPercentage(int x) => x is >= 0 and <= 100;
```

But when the input is not such a primitive type, what type do we attempt to convert it to?

```
c#
```

```
bool IsValidPercentage(object x) => x is >= 0 and <= 100;
```

We have proposed that when the input type is already a comparable primitive, that is the type of the comparison. However, when the input is not a comparable primitive, we treat the relational as including an implicit type test to the type of the constant on the right-hand-side of the relational. If the programmer intends to support more than one input type, that must be done explicitly:

```
c#
```

```
bool IsValidPercentage(object x) => x is  
    >= 0 and <= 100 or // integer tests
```

```
>= 0F and <= 100F or // float tests
>= 0D and <= 100D; // double tests
```

Flowing type information from the left to the right of `and`

It has been suggested that when you write an `and` combinator, type information learned on the left about the top-level type could flow to the right. For example

C#

```
bool isSmallByte(object o) => o is byte and < 100;
```

Here, the *input type* to the second pattern is narrowed by the *type narrowing* requirements of left of the `and`. We would define type narrowing semantics for all patterns as follows. The *narrowed type* of a pattern `P` is defined as follows:

1. If `P` is a type pattern, the *narrowed type* is the type of the type pattern's type.
2. If `P` is a declaration pattern, the *narrowed type* is the type of the declaration pattern's type.
3. If `P` is a recursive pattern that gives an explicit type, the *narrowed type* is that type.
4. If `P` is [matched via the rules for](#) `ITuple`, the *narrowed type* is the type `System.Runtime.CompilerServices.ITuple`.
5. If `P` is a constant pattern where the constant is not the null constant and where the expression has no *constant expression conversion* to the *input type*, the *narrowed type* is the type of the constant.
6. If `P` is a relational pattern where the constant expression has no *constant expression conversion* to the *input type*, the *narrowed type* is the type of the constant.
7. If `P` is an `or` pattern, the *narrowed type* is the common type of the *narrowed type* of the subpatterns if such a common type exists. For this purpose, the common type algorithm considers only identity, boxing, and implicit reference conversions, and it considers all subpatterns of a sequence of `or` patterns (ignoring parenthesized patterns).
8. If `P` is an `and` pattern, the *narrowed type* is the *narrowed type* of the right pattern. Moreover, the *narrowed type* of the left pattern is the *input type* of the right pattern.
9. Otherwise the *narrowed type* of `P` is `P`'s input type.

Variable definitions and definite assignment

The addition of `or` and `not` patterns creates some interesting new problems around pattern variables and definite assignment. Since variables can normally be declared at most once, it would seem any pattern variable declared on one side of an `or` pattern would not be definitely assigned when the pattern matches. Similarly, a variable declared inside a `not` pattern would not be expected to be definitely assigned when the pattern matches. The simplest way to address this is to forbid declaring pattern variables in these contexts. However, this may be too restrictive. There are other approaches to consider.

One scenario that is worth considering is this

```
C#  
  
if (e is not int i) return;  
M(i); // is i definitely assigned here?
```

This does not work today because, for an *is-pattern-expression*, the pattern variables are considered *definitely assigned* only where the *is-pattern-expression* is true ("definitely assigned when true").

Supporting this would be simpler (from the programmer's perspective) than also adding support for a negated-condition `if` statement. Even if we add such support, programmers would wonder why the above snippet does not work. On the other hand, the same scenario in a `switch` makes less sense, as there is no corresponding point in the program where *definitely assigned when false* would be meaningful. Would we permit this in an *is-pattern-expression* but not in other contexts where patterns are permitted? That seems irregular.

Related to this is the problem of definite assignment in a *disjunctive-pattern*.

```
C#  
  
if (e is 0 or int i)  
{  
    M(i); // is i definitely assigned here?  
}
```

We would only expect `i` to be definitely assigned when the input is not zero. But since we don't know whether the input is zero or not inside the block, `i` is not definitely assigned. However, what if we permit `i` to be declared in different mutually exclusive patterns?

```
C#
```

```
if ((e1, e2) is (0, int i) or (int i, 0))
{
    M(i);
}
```

Here, the variable `i` is definitely assigned inside the block, and takes its value from the other element of the tuple when a zero element is found.

It has also been suggested to permit variables to be (multiply) defined in every case of a case block:

```
C#
case (0, int x):
case (int x, 0):
    Console.WriteLine(x);
```

To make any of this work, we would have to carefully define where such multiple definitions are permitted and under what conditions such a variable is considered definitely assigned.

Should we elect to defer such work until later (which I advise), we could say in C# 9

- beneath a `not` or `or`, pattern variables may not be declared.

Then, we would have time to develop some experience that would provide insight into the possible value of relaxing that later.

Diagnostics, subsumption, and exhaustiveness

These new pattern forms introduce many new opportunities for diagnosable programmer error. We will need to decide what kinds of errors we will diagnose, and how to do so. Here are some examples:

```
C#
case >= 0 and <= 100D:
```

This case can never match (because the input cannot be both an `int` and a `double`). We already have an error when we detect a case that can never match, but its wording ("The switch case has already been handled by a previous case" and "The pattern has already been handled by a previous arm of the switch expression") may be misleading in new scenarios. We may have to modify the wording to just say that the pattern will never match the input.

```
C#
```

```
case 1 and 2:
```

Similarly, this would be an error because a value cannot be both 1 and 2.

```
C#
```

```
case 1 or 2 or 3 or 1:
```

This case is possible to match, but the `or 1` at the end adds no meaning to the pattern. I suggest we should aim to produce an error whenever some conjunct or disjunct of a compound pattern does not either define a pattern variable or affect the set of matched values.

```
C#
```

```
case < 2: break;  
case 0 or 1 or 2 or 3 or 4 or 5: break;
```

Here, `0 or 1 or` adds nothing to the second case, as those values would have been handled by the first case. This too deserves an error.

```
C#
```

```
byte b = ...;  
int x = b switch { <100 => 0, 100 => 1, 101 => 2, >101 => 3 };
```

A switch expression such as this should be considered *exhaustive* (it handles all possible input values).

In C# 8.0, a switch expression with an input of type `byte` is only considered exhaustive if it contains a final arm whose pattern matches everything (a *discard-pattern* or *var-pattern*). Even a switch expression that has an arm for every distinct `byte` value is not considered exhaustive in C# 8. In order to properly handle exhaustiveness of relational patterns, we will have to handle this case too. This will technically be a breaking change, but no user is likely to notice.

Init Only Setters

Article • 2021-09-21 • 15 minutes to read

Summary

This proposal adds the concept of init only properties and indexers to C#. These properties and indexers can be set at the point of object creation but become effectively `get` only once object creation has completed. This allows for a much more flexible immutable model in C#.

Motivation

The underlying mechanisms for building immutable data in C# haven't changed since 1.0. They remain:

1. Declaring fields as `readonly`.
2. Declaring properties that contain only a `get` accessor.

These mechanisms are effective at allowing the construction of immutable data but they do so by adding cost to the boilerplate code of types and opting such types out of features like object and collection initializers. This means developers must choose between ease of use and immutability.

A simple immutable object like `Point` requires twice as much boiler plate code to support construction as it does to declare the type. The bigger the type the bigger the cost of this boiler plate:

C#

```
struct Point
{
    public int X { get; }
    public int Y { get; }

    public Point(int x, int y)
    {
        this.X = x;
        this.Y = y;
    }
}
```

The `init` accessor makes immutable objects more flexible by allowing the caller to mutate the members during the act of construction. That means the object's immutable properties can participate in object initializers and thus removes the need for all constructor boilerplate in the type. The `Point` type is now simply:

```
C#  
  
struct Point  
{  
    public int X { get; init; }  
    public int Y { get; init; }  
}
```

The consumer can then use object initializers to create the object

```
C#  
  
var p = new Point() { X = 42, Y = 13 };
```

Detailed Design

init accessors

An `init` only property (or indexer) is declared by using the `init` accessor in place of the `set` accessor:

```
C#  
  
class Student  
{  
    public string FirstName { get; init; }  
    public string LastName { get; init; }  
}
```

An instance property containing an `init` accessor is considered settable in the following circumstances, except when in a local function or lambda:

- During an object initializer
- During a `with` expression initializer
- Inside an instance constructor of the containing or derived type, on `this` or `base`
- Inside the `init` accessor of any property, on `this` or `base`
- Inside attribute usages with named parameters

The times above in which the `init` accessors are settable are collectively referred to in this document as the construction phase of the object.

This means the `Student` class can be used in the following ways:

C#

```
var s = new Student()
{
    FirstName = "Jared",
    LastName = "Parosns",
};
s.LastName = "Parsons"; // Error: LastName is not settable
```

The rules around when `init` accessors are settable extend across type hierarchies. If the member is accessible and the object is known to be in the construction phase then the member is settable. That specifically allows for the following:

C#

```
class Base
{
    public bool Value { get; init; }
}

class Derived : Base
{
    Derived()
    {
        // Not allowed with get only properties but allowed with init
        Value = true;
    }
}

class Consumption
{
    void Example()
    {
        var d = new Derived() { Value = true; };
    }
}
```

At the point an `init` accessor is invoked, the instance is known to be in the open construction phase. Hence an `init` accessor is allowed to take the following actions in addition to what a normal `set` accessor can do:

1. Call other `init` accessors available through `this` or `base`

2. Assign `readonly` fields declared on the same type through `this`

```
C#  
  
class Complex  
{  
    readonly int Field1;  
    int Field2;  
    int Prop1 { get; init; }  
    int Prop2  
    {  
        get => 42;  
        init  
        {  
            Field1 = 13; // okay  
            Field2 = 13; // okay  
            Prop1 = 13; // okay  
        }  
    }  
}
```

The ability to assign `readonly` fields from an `init` accessor is limited to those fields declared on the same type as the accessor. It cannot be used to assign `readonly` fields in a base type. This rule ensures that type authors remain in control over the mutability behavior of their type. Developers who do not wish to utilize `init` cannot be impacted from other types choosing to do so:

```
C#  
  
class Base  
{  
    internal readonly int Field;  
    internal int Property  
    {  
        get => Field;  
        init => Field = value; // Okay  
    }  
  
    internal int OtherProperty { get; init; }  
}  
  
class Derived : Base  
{  
    internal readonly int DerivedField;  
    internal int DerivedProperty  
    {  
        get => DerivedField;  
        init  
        {  
            DerivedField = 42; // Okay  
            Property = 0; // Okay  
        }  
    }  
}
```

```

        Field = 13;           // Error Field is readonly
    }
}

public Derived()
{
    Property = 42; // Okay
    Field = 13;   // Error Field is readonly
}
}

```

When `init` is used in a virtual property then all the overrides must also be marked as `init`. Likewise it is not possible to override a simple `set` with `init`.

```

C#

class Base
{
    public virtual int Property { get; init; }
}

class C1 : Base
{
    public override int Property { get; init; }
}

class C2 : Base
{
    // Error: Property must have init to override Base.Property
    public override int Property { get; set; }
}

```

An `interface` declaration can also participate in `init` style initialization via the following pattern:

```

C#

interface IPerson
{
    string Name { get; init; }
}

class Init
{
    void M<T>() where T : IPerson, new()
    {
        var local = new T()
        {
            Name = "Jared"
        };
        local.Name = "Jraed"; // Error
    }
}

```

```
}  
}
```

Restrictions of this feature:

- The `init` accessor can only be used on instance properties
- A property cannot contain both an `init` and `set` accessor
- All overrides of a property must have `init` if the base had `init`. This rule also applies to interface implementation.

Readonly structs

`init` accessors (both auto-implemented accessors and manually-implemented accessors) are permitted on properties of `readonly structs`, as well as `readonly` properties. `init` accessors are not permitted to be marked `readonly` themselves, in both `readonly` and non-`readonly struct` types.

```
C#
```

```
readonly struct ReadonlyStruct1  
{  
    public int Prop1 { get; init; } // Allowed  
}  
  
struct ReadonlyStruct2  
{  
    public readonly int Prop2 { get; init; } // Allowed  
  
    public int Prop3 { get; readonly init; } // Error  
}
```

Metadata encoding

Property `init` accessors will be emitted as a standard `set` accessor with the return type marked with a modreq of `IsExternalInit`. This is a new type which will have the following definition:

```
C#
```

```
namespace System.Runtime.CompilerServices  
{  
    public sealed class IsExternalInit  
    {  
    }  
}
```

The compiler will match the type by full name. There is no requirement that it appear in the core library. If there are multiple types by this name then the compiler will tie break in the following order:

1. The one defined in the project being compiled
2. The one defined in corelib

If neither of these exist then a type ambiguity error will be issued.

The design for `IsExternalInit` is further covered in [this issue](#) [↗](#)

Questions

Breaking changes

One of the main pivot points in how this feature is encoded will come down to the following question:

Is it a binary breaking change to replace `init` with `set`?

Replacing `init` with `set` and thus making a property fully writable is never a source breaking change on a non-virtual property. It simply expands the set of scenarios where the property can be written. The only behavior in question is whether or not this remains a binary breaking change.

If we want to make the change of `init` to `set` a source and binary compatible change then it will force our hand on the modreq vs. attributes decision below because it will rule out modreqs as a solution. If on the other hand this is seen as a non-interesting then this will make the modreq vs. attribute decision less impactful.

Resolution This scenario is not seen as compelling by LDM.

Modreqs vs. attributes

The emit strategy for `init` property accessors must choose between using attributes or modreqs when emitting during metadata. These have different trade offs that need to be considered.

Annotating a property set accessor with a modreq declaration means CLI compliant compilers will ignore the accessor unless it understands the modreq. That means only

compilers aware of `init` will read the member. Compilers unaware of `init` will ignore the `set` accessor and hence will not accidentally treat the property as read / write.

The downside of `modreq` is `init` becomes a part of the binary signature of the `set` accessor. Adding or removing `init` will break binary compatibility of the application.

Using attributes to annotate the `set` accessor means that only compilers which understand the attribute will know to limit access to it. A compiler unaware of `init` will see it as a simple read / write property and allow access.

This would seemingly mean this decision is a choice between extra safety at the expense of binary compatibility. Digging in a bit the extra safety is not exactly what it seems. It will not protect against the following circumstances:

1. Reflection over `public` members
2. The use of `dynamic`
3. Compilers that don't recognize `modreqs`

It should also be considered that, when we complete the IL verification rules for .NET 5, `init` will be one of those rules. That means extra enforcement will be gained from simply verifying compilers emitting verifiable IL.

The primary languages for .NET (C#, F# and VB) will all be updated to recognize these `init` accessors. Hence the only realistic scenario here is when a C# 9 compiler emits `init` properties and they are seen by an older toolset such as C# 8, VB 15, etc ... C# 8. That is the trade off to consider and weigh against binary compatibility.

Note This discussion primarily applies to members only, not to fields. While `init` fields were rejected by LDM they are still interesting to consider for the `modreq` vs. attribute discussion. The `init` feature for fields is a relaxation of the existing restriction of `readonly`. That means if we emit the fields as `readonly` + an attribute there is no risk of older compilers mis-using the field because they would already recognize `readonly`. Hence using a `modreq` here doesn't add any extra protection.

Resolution The feature will use a `modreq` to encode the property `init` setter. The compelling factors were (in no particular order):

- Desire to discourage older compilers from violating `init` semantics
- Desire to make adding or removing `init` in a `virtual` declaration or `interface` both a source and binary breaking change.

Given there was also no significant support for removing `init` to be a binary compatible change it made the choice of using `modreq` straight forward.

init vs. initonly

There were three syntax forms which got significant consideration during our LDM meeting:

```
C#  
  
// 1. Use init  
int Option1 { get; init; }  
// 2. Use init set  
int Option2 { get; init set; }  
// 3. Use initonly  
int Option3 { get; initonly; }
```

Resolution There was no syntax which was overwhelmingly favored in LDM.

One point which got significant attention was how the choice of syntax would impact our ability to do `init` members as a general feature in the future. Choosing option 1 would mean that it would be difficult to define a property which had an `init` style `get` method in the future. Eventually it was decided that if we decided to go forward with general `init` members in future, we could allow `init` to be a modifier in the property accessor list as well as a short hand for `init set`. Essentially the following two declarations would be identical.

```
C#  
  
int Property1 { get; init; }  
int Property1 { get; init set; }
```

The decision was made to move forward with `init` as a standalone accessor in the property accessor list.

Warn on failed init

Consider the following scenario. A type declares an `init` only member which is not set in the constructor. Should the code which constructs the object get a warning if they failed to initialize the value?

At that point it is clear the field will never be set and hence has a lot of similarities with the warning around failing to initialize `private` data. Hence a warning would seemingly have some value here?

There are significant downsides to this warning though:

1. It complicates the compatibility story of changing `readonly` to `init`.
2. It requires carrying additional metadata around to denote the members which are required to be initialized by the caller.

Further if we believe there is value here in the overall scenario of forcing object creators to be warned / error'd about specific fields then this likely makes sense as a general feature. There is no reason it should be limited to just `init` members.

Resolution There will be no warning on consumption of `init` fields and properties.

LDM wants to have a broader discussion on the idea of required fields and properties. That may cause us to come back and reconsider our position on `init` members and validation.

Allow `init` as a field modifier

In the same way `init` can serve as a property accessor it could also serve as a designation on fields to give them similar behaviors as `init` properties. That would allow for the field to be assigned before construction was complete by the type, derived types, or object initializers.

```
C#  
  
class Student  
{  
    public init string FirstName;  
    public init string LastName;  
}  
  
var s = new Student()  
{  
    FirstName = "Jarde",  
    LastName = "Parsons",  
}  
  
s.FirstName = "Jared"; // Error FirstName is readonly
```

In metadata these fields would be marked in the same way as `readonly` fields but with an additional attribute or `modreq` to indicate they are `init` style fields.

Resolution LDM agrees this proposal is sound but overall the scenario felt disjoint from properties. The decision was to proceed only with `init` properties for now. This has a suitable level of flexibility as an `init` property can mutate a `readonly` field on the

declaring type of the property. This will be reconsidered if there is significant customer feedback that justifies the scenario.

Allow `init` as a type modifier

In the same way the `readonly` modifier can be applied to a `struct` to automatically declare all fields as `readonly`, the `init` only modifier can be declared on a `struct` or `class` to automatically mark all fields as `init`. This means the following two type declarations are equivalent:

```
C#  
  
struct Point  
{  
    public init int X;  
    public init int Y;  
}  
  
// vs.  
  
init struct Point  
{  
    public int X;  
    public int Y;  
}
```

Resolution This feature is too *cute* here and conflicts with the `readonly struct` feature on which it is based. The `readonly struct` feature is simple in that it applies `readonly` to all members: fields, methods, etc ... The `init struct` feature would only apply to properties. This actually ends up making it confusing for users.

Given that `init` is only valid on certain aspects of a type, we rejected the idea of having it as a type modifier.

Considerations

Compatibility

The `init` feature is designed to be compatible with existing `get` only properties. Specifically it is meant to be a completely additive change for a property which is `get` only today but desires more flexible object creation semantics.

For example consider the following type:

C#

```
class Name
{
    public string First { get; }
    public string Last { get; }

    public Name(string first, string last)
    {
        First = first;
        Last = last;
    }
}
```

Adding `init` to these properties is a non-breaking change:

C#

```
class Name
{
    public string First { get; init; }
    public string Last { get; init; }

    public Name(string first, string last)
    {
        First = first;
        Last = last;
    }
}
```

IL verification

When .NET Core decides to re-implement IL verification, the rules will need to be adjusted to account for `init` members. This will need to be included in the rule changes for non-mutating access to `readonly` data.

The IL verification rules will need to be broken into two parts:

1. Allowing `init` members to set a `readonly` field.
2. Determining when an `init` member can be legally called.

The first is a simple adjustment to the existing rules. The IL verifier can be taught to recognize `init` members and from there it just needs to consider a `readonly` field to be settable on `this` in such a member.

The second rule is more complicated. In the simple case of object initializers the rule is straight forward. It should be legal to call `init` members when the result of a `new`

expression is still on the stack. That is until the value has been stored in a local, array element or field or passed as an argument to another method it will still be legal to call `init` members. This ensures that once the result of the `new` expression is published to a named identifier (other than `this`) then it will no longer be legal to call `init` members.

The more complicated case though is when we mix `init` members, object initializers and `await`. That can cause the newly created object to be temporarily hoisted into a state machine and hence put into a field.

C#

```
var student = new Student()
{
    Name = await SomeMethod()
};
```

Here the result of `new Student()` will be hoisted into a state machine as a field before the set of `Name` occurs. The compiler will need to mark such hoisted fields in a way that the IL verifier understands they're not user accessible and hence doesn't violate the intended semantics of `init`.

init members

The `init` modifier could be extended to apply to all instance members. This would generalize the concept of `init` during object construction and allow types to declare helper methods that could participate in the construction process to initialize `init` fields and properties.

Such members would have all the restrictions that an `init` accessor does in this design. The need is questionable though and this can be safely added in a future version of the language in a compatible manner.

Generate three accessors

One potential implementation of `init` properties is to make `init` completely separate from `set`. That means that a property can potentially have three different accessors: `get`, `set`, and `init`.

This has the potential advantage of allowing the use of `modreq` to enforce correctness while maintaining binary compatibility. The implementation would roughly be the following:

1. An `init` accessor is always emitted if there is a `set`. When not defined by the developer it is simply a reference to `set`.
2. The set of a property in an object initializer will always use `init` if present but fall back to `set` if it's missing.

This means that a developer can always safely delete `init` from a property.

The downside of this design is that is only useful if `init` is **always** emitted when there is a `set`. The language can't know if `init` was deleted in the past, it has to assume it was and hence the `init` must always be emitted. That would cause a significant metadata expansion and is simply not worth the cost of the compatibility here.

Target-typed `new` expressions

Article • 2021-09-21 • 3 minutes to read

Summary

Do not require type specification for constructors when the type is known.

Motivation

Allow field initialization without duplicating the type.

```
C#  
  
Dictionary<string, List<int>> field = new() {  
    { "item1", new() { 1, 2, 3 } }  
};
```

Allow omitting the type when it can be inferred from usage.

```
C#  
  
XmlReader.Create(reader, new() { IgnoreWhitespace = true });
```

Instantiate an object without spelling out the type.

```
C#  
  
private readonly static object s_syncObj = new();
```

Specification

A new syntactic form, *target_typed_new* of the *object_creation_expression* is accepted in which the *type* is optional.

```
antlr  
  
object_creation_expression  
    : 'new' type '(' argument_list? ')' object_or_collection_initializer?  
    | 'new' type object_or_collection_initializer  
    | target_typed_new  
    ;  
target_typed_new
```

```
: 'new' '(' argument_list? ')' object_or_collection_initializer?  
;
```

A *target_typed_new* expression does not have a type. However, there is a new *object creation conversion* that is an implicit conversion from expression, that exists from a *target_typed_new* to every type.

Given a target type T , the type T_0 is T 's underlying type if T is an instance of `System.Nullable`. Otherwise T_0 is T . The meaning of a *target_typed_new* expression that is converted to the type T is the same as the meaning of a corresponding *object_creation_expression* that specifies T_0 as the type.

It is a compile-time error if a *target_typed_new* is used as an operand of a unary or binary operator, or if it is used where it is not subject to an *object creation conversion*.

Open Issue: should we allow delegates and tuples as the target-type?

The above rules include delegates (a reference type) and tuples (a struct type). Although both types are constructible, if the type is inferable, an anonymous function or a tuple literal can already be used.

C#

```
(int a, int b) t = new(1, 2); // "new" is redundant  
Action a = new(() => {}); // "new" is redundant  
  
(int a, int b) t = new(); // OK; same as (0, 0)  
Action a = new(); // no constructor found
```

Miscellaneous

The following are consequences of the specification:

- `throw new()` is allowed (the target type is `System.Exception`)
- Target-typed `new` is not allowed with binary operators.
- It is disallowed when there is no type to target: unary operators, collection of a `foreach`, in a `using`, in a deconstruction, in an `await` expression, as an anonymous type property (`new { Prop = new() }`), in a `lock` statement, in a `sizeof`, in a `fixed` statement, in a member access (`new().field`), in a dynamically dispatched operation (`someDynamic.Method(new())`), in a LINQ query, as the operand of the `is` operator, as the left operand of the `??` operator, ...
- It is also disallowed as a `ref`.

- The following kinds of types are not permitted as targets of the conversion
 - **Enum types:** `new()` will work (as `new Enum()` works to give the default value), but `new(1)` will not work as enum types do not have a constructor.
 - **Interface types:** This would work the same as the corresponding creation expression for COM types.
 - **Array types:** arrays need a special syntax to provide the length.
 - **dynamic:** we don't allow `new dynamic()`, so we don't allow `new()` with `dynamic` as a target type.
 - **tuples:** These have the same meaning as an object creation using the underlying type.
 - All the other types that are not permitted in the *object_creation_expression* are excluded as well, for instance, pointer types.

Drawbacks

There were some concerns with target-typed `new` creating new categories of breaking changes, but we already have that with `null` and `default`, and that has not been a significant problem.

Alternatives

Most of complaints about types being too long to duplicate in field initialization is about *type arguments* not the type itself, we could infer only type arguments like `new Dictionary(...)` (or similar) and infer type arguments locally from arguments or the collection initializer.

Questions

- Should we forbid usages in expression trees? (no)
- How the feature interacts with `dynamic` arguments? (no special treatment)
- How IntelliSense should work with `new()`? (only when there is a single target-type)

Module Initializers

Article • 2021-09-21 • 2 minutes to read

Summary

Although the .NET platform has a [feature](#) that directly supports writing initialization code for the assembly (technically, the module), it is not exposed in C#. This is a rather niche scenario, but once you run into it the solutions appear to be pretty painful. There are reports of [a number of customers](#) (inside and outside Microsoft) struggling with the problem, and there are no doubt more undocumented cases.

Motivation

- Enable libraries to do eager, one-time initialization when loaded, with minimal overhead and without the user needing to explicitly call anything
- One particular pain point of current `static` constructor approaches is that the runtime must do additional checks on usage of a type with a static constructor, in order to decide whether the static constructor needs to be run or not. This adds measurable overhead.
- Enable source generators to run some global initialization logic without the user needing to explicitly call anything

Detailed design

A method can be designated as a module initializer by decorating it with a `[ModuleInitializer]` attribute.

C#

```
using System;
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Method, AllowMultiple = false)]
    public sealed class ModuleInitializerAttribute : Attribute { }
}
```

The attribute can be used like this:

C#

```
using System.Runtime.CompilerServices;
class C
{
    [ModuleInitializer]
    internal static void M1()
    {
        // ...
    }
}
```

Some requirements are imposed on the method targeted with this attribute:

1. The method must be `static`.
2. The method must be parameterless.
3. The method must return `void`.
4. The method must not be generic or be contained in a generic type.
5. The method must be accessible from the containing module.
 - This means the method's effective accessibility must be `internal` or `public`.
 - This also means the method cannot be a local function.

When one or more valid methods with this attribute are found in a compilation, the compiler will emit a module initializer which calls each of the attributed methods. The calls will be emitted in a reserved, but deterministic order.

Drawbacks

Why should we *not* do this?

- Perhaps the existing third-party tooling for "injecting" module initializers is sufficient for users who have been asking for this feature.

Extending Partial Methods

Article • 2022-02-23 • 5 minutes to read

Summary

This proposal aims to remove all restrictions around the signatures of `partial` methods in C#. The goal being to expand the set of scenarios in which these methods can work with source generators as well as being a more general declaration form for C# methods.

See also the original partial methods specification ([§14.6.9](#)).

Motivation

C# has limited support for developers splitting methods into declarations and definitions / implementations.

C#

```
partial class C
{
    // The declaration of C.M
    partial void M(string message);
}

partial class C
{
    // The definition of C.M
    partial void M(string message) => Console.WriteLine(message);
}
```

One behavior of `partial` methods is that when the definition is absent then the language will simply erase any calls to the `partial` method. Essentially it behaves like a call to a `[Conditional]` method where the condition was evaluated to false.

C#

```
partial class D
{
    partial void M(string message);

    void Example()
    {
        M(GetIt()); // Call to M and GetIt erased at compile time
    }
}
```

```
}  
  
    string GetIt() => "Hello World";  
}
```

The original motivation for this feature was source generation in the form of designer generated code. Users were constantly editing the generated code because they wanted to hook some aspect of the generated code. Most notably parts of the Windows Forms startup process, after components were initialized.

Editing the generated code was error prone because any action which caused the designer to regenerate the code would cause the user edit to be erased. The `partial` method feature eased this tension because it allowed designers to emit hooks in the form of `partial` methods.

Designers could emit hooks like `partial void OnComponentInit()` and developers could define declarations for them or not define them. In either case though the generated code would compile and developers who were interested in the process could hook in as needed.

This does mean that partial methods have several restrictions:

1. Must have a `void` return type.
2. Cannot have `out` parameters.
3. Cannot have any accessibility (implicitly `private`).

These restrictions exist because the language must be able to emit code when the call site is erased. Given they can be erased `private` is the only possible accessibility because the member can't be exposed in assembly metadata. These restrictions also serve to limit the set of scenarios in which `partial` methods can be applied.

The proposal here is to remove all of the existing restrictions around `partial` methods. Essentially let them have `out`, non-void return types or any type of accessibility. Such `partial` declarations would then have the added requirement that a definition must exist. That means the language does not have to consider the impact of erasing the call sites.

This would expand the set of generator scenarios that `partial` methods could participate in and hence link in nicely with our source generators feature. For example a regex could be defined using the following pattern:

```
C#
```

```
[RegexGenerated("(dog|cat|fish)")]
partial bool IsPetMatch(string input);
```

This gives both the developer a simple declarative way of opting into generators as well as giving generators a very easy set of declarations to look through in the source code to drive their generated output.

Compare that with the difficulty that a generator would have hooking up the following snippet of code.

```
C#

var regex = new RegularExpression("(dog|cat|fish)");
if (regex.IsMatch(someInput))
{
}
}
```

Given that the compiler doesn't allow generators to modify code hooking up this pattern would be pretty much impossible for generators. They would need to resort to reflection in the `IsMatch` implementation, or asking users to change their call sites to a new method + refactor the regex to pass the string literal as an argument. It's pretty messy.

Detailed Design

The language will change to allow `partial` methods to be annotated with an explicit accessibility modifier. This means they can be labeled as `private`, `public`, etc ...

When a `partial` method has an explicit accessibility modifier though the language will require that the declaration has a matching definition even when the accessibility is `private`:

```
C#

partial class C
{
    // Okay because no definition is required here
    partial void M1();

    // Okay because M2 has a definition
    private partial void M2();

    // Error: partial method M3 must have a definition
    private partial void M3();
}
```

```

}

partial class C
{
    private partial void M2() { }
}

```

Further the language will remove all restrictions on what can appear on a `partial` method which has an explicit accessibility. Such declarations can contain non-void return types, `out` parameters, `extern` modifier, etc ... These signatures will have the full expressivity of the C# language.

```

C#

partial class D
{
    // Okay
    internal partial bool TryParse(string s, out int i);
}

partial class D
{
    internal partial bool TryParse(string s, out int i) { }
}

```

This explicitly allows for `partial` methods to participate in `overrides` and `interface` implementations:

```

C#

interface IStudent
{
    string GetName();
}

partial class C : IStudent
{
    public virtual partial string GetName();
}

partial class C
{
    public virtual partial string GetName() => "Jarde";
}

```

The compiler will change the error it emits when a `partial` method contains an illegal element to essentially say:

Cannot use `ref` on a `partial` method that lacks explicit accessibility

This will help point developers in the right direction when using this feature.

Restrictions:

- `partial` declarations with explicit accessibility must have a definition
- `partial` declarations and definition signatures must match on all method and parameter modifiers. The only aspects which can differ are parameter names and attribute lists (this is not new but rather an existing requirement of `partial` methods).

Questions

partial on all members

Given that we're expanding `partial` to be more friendly to source generators should we also expand it to work on all class members? For example should we be able to declare `partial` constructors, operators, etc ...

Resolution The idea is sound but at this point in the C# 9 schedule we're trying to avoid unnecessary feature creep. Want to solve the immediate problem of expanding the feature to work with modern source generators.

Extending `partial` to support other members will be considered for the C# 10 release. Seems likely that we will consider this extension.

Use abstract instead of partial

The crux of this proposal is essentially ensuring that a declaration has a corresponding definition / implementation. Given that should we use `abstract` since it's already a language keyword that forces the developer to think about having an implementation?

Resolution There was a healthy discussion about this but eventually it was decided against. Yes the requirements are familiar but the concepts are significantly different. Could easily lead the developer to believe they were creating virtual slots when they were not doing so.

Static anonymous functions

Article • 2021-09-21 • 2 minutes to read

Summary

Allow a 'static' modifier on lambdas and anonymous methods, which disallows capture of locals or instance state from containing scopes.

Motivation

Avoid unintentionally capturing state from the enclosing context, which can result in unexpected retention of captured objects or unexpected additional allocations.

Detailed design

A lambda or anonymous method may have a `static` modifier. The `static` modifier indicates that the lambda or anonymous method is a *static anonymous function*.

A *static anonymous function* cannot capture state from the enclosing scope. As a result, locals, parameters, and `this` from the enclosing scope are not available within a *static anonymous function*.

A *static anonymous function* cannot reference instance members from an implicit or explicit `this` or `base` reference.

A *static anonymous function* may reference `static` members from the enclosing scope.

A *static anonymous function* may reference `constant` definitions from the enclosing scope.

`nameof()` in a *static anonymous function* may reference locals, parameters, or `this` or `base` from the enclosing scope.

Accessibility rules for `private` members in the enclosing scope are the same for `static` and non-`static` anonymous functions.

No guarantee is made as to whether a *static anonymous function* definition is emitted as a `static` method in metadata. This is left up to the compiler implementation to optimize.

A non-`static` local function or anonymous function can capture state from an enclosing *static anonymous function* but cannot capture state outside the enclosing *static anonymous function*.

Removing the `static` modifier from an anonymous function in a valid program does not change the meaning of the program.

Target-Typed Conditional Expression

Article • 2022-02-23 • 3 minutes to read

Conditional Expression Conversion

For a conditional expression $c ? e_1 : e_2$, when

1. there is no common type for e_1 and e_2 , or
2. for which a common type exists but one of the expressions e_1 or e_2 has no implicit conversion to that type

we define a new implicit *conditional expression conversion* that permits an implicit conversion from the conditional expression to any type T for which there is a conversion-from-expression from e_1 to T and also from e_2 to T . It is an error if a conditional expression neither has a common type between e_1 and e_2 nor is subject to a *conditional expression conversion*.

Better Conversion from Expression

We change

Better conversion from expression

Given an implicit conversion c_1 that converts from an expression E to a type T_1 , and an implicit conversion c_2 that converts from an expression E to a type T_2 , c_1 is a **better conversion** than c_2 if E does not exactly match T_2 and at least one of the following holds:

- E exactly matches T_1 ([§11.6.4.4](#))
- T_1 is a better conversion target than T_2 ([§11.6.4.6](#))

to

Better conversion from expression

Given an implicit conversion c_1 that converts from an expression E to a type T_1 , and an implicit conversion c_2 that converts from an expression E to a type T_2 , c_1

is a **better conversion** than `C2` if `E` does not exactly match `T2` and at least one of the following holds:

- `E` exactly matches `T1` ([§11.6.4.4](#))
- `C1` is not a **conditional expression conversion** and `C2` is a **conditional expression conversion**.
- `T1` is a better conversion target than `T2` ([§11.6.4.6](#)) and either `C1` and `C2` are both **conditional expression conversions** or neither is a **conditional expression conversion**.

Cast Expression

The current C# language specification says

A *cast_expression* of the form `(T)E`, where `T` is a *type* and `E` is a *unary_expression*, performs an explicit conversion ([§10.3](#)) of the value of `E` to type `T`.

In the presence of the *conditional expression conversion* there may be more than one possible conversion from `E` to `T`. With the addition of *conditional expression conversion*, we prefer any other conversion to a *conditional expression conversion*, and use the *conditional expression conversion* only as a last resort.

Design Notes

The reason for the change to *Better conversion from expression* is to handle a case such as this:

```
C#  
  
M(b ? 1 : 2);  
  
void M(short);  
void M(long);
```

This approach does have two small downsides. First, it is not quite the same as the switch expression:

```
C#  
  
M(b ? 1 : 2); // calls M(long)  
M(b switch { true => 1, false => 2 }); // calls M(short)
```

This is still a breaking change, but its scope is less likely to affect real programs:

```
C#
```

```
M(b ? 1 : 2, 1); // calls M(long, long) without this feature; ambiguous with this feature.
```

```
M(short, short);  
M(long, long);
```

This becomes ambiguous because the conversion to `long` is better for the first argument (because it does not use the *conditional expression conversion*), but the conversion to `short` is better for the second argument (because `short` is a *better conversion target* than `long`). This breaking change seems less serious because it does not silently change the behavior of an existing program.

The reason for the notes on the cast expression is to handle a case such as this:

```
C#
```

```
_ = (short)(b ? 1 : 2);
```

This program currently uses the explicit conversion from `int` to `short`, and we want to preserve the current language meaning of this program. The change would be unobservable at runtime, but with the following program the change would be observable:

```
C#
```

```
_ = (A)(b ? c : d);
```

where `c` is of type `C`, `d` is of type `D`, and there is an implicit user-defined conversion from `C` to `D`, and an implicit user-defined conversion from `D` to `A`, and an implicit user-defined conversion from `C` to `A`. If this code is compiled before C# 9.0, when `b` is true we convert from `c` to `D` then to `A`. If we use the *conditional expression conversion*, then when `b` is true we convert from `c` to `A` directly, which executes a different sequence of user code. Therefore we treat the *conditional expression conversion* as a last resort in a cast, to preserve existing behavior.

Covariant returns

Article • 2022-02-23 • 10 minutes to read

Summary

Support *covariant return types*. Specifically, permit the override of a method to declare a more derived return type than the method it overrides, and similarly to permit the override of a read-only property to declare a more derived type. Override declarations appearing in more derived types would be required to provide a return type at least as specific as that appearing in overrides in its base types. Callers of the method or property would statically receive the more refined return type from an invocation.

Motivation

It is a common pattern in code that different method names have to be invented to work around the language constraint that overrides must return the same type as the overridden method.

This would be useful in the factory pattern. For example, in the Roslyn code base we would have

C#

```
class Compilation ...
{
    public virtual Compilation WithOptions(Options options)...
}
```

C#

```
class CSharpCompilation : Compilation
{
    public override CSharpCompilation WithOptions(Options options)...
}
```

Detailed design

This is a specification for [covariant return types](#) in C#. Our intent is to permit the override of a method to return a more derived return type than the method it overrides, and similarly to permit the override of a read-only property to return a more derived

return type. Callers of the method or property would statically receive the more refined return type from an invocation, and overrides appearing in more derived types would be required to provide a return type at least as specific as that appearing in overrides in its base types.

Class Method Override

The existing constraint on class override ([§14.6.5](#)) methods

- The override method and the overridden base method have the same return type.

is modified to

- The override method must have a return type that is convertible by an identity conversion or (if the method has a value return - not a [ref return](#)) implicit reference conversion to the return type of the overridden base method.

And the following additional requirements are appended to that list:

- The override method must have a return type that is convertible by an identity conversion or (if the method has a value return - not a [ref return](#)) implicit reference conversion to the return type of every override of the overridden base method that is declared in a (direct or indirect) base type of the override method.
- The override method's return type must be at least as accessible as the override method ([Accessibility domains - §7.5.3](#)).

This constraint permits an override method in a `private` class to have a `private` return type. However it requires a `public` override method in a `public` type to have a `public` return type.

Class Property and Indexer Override

The existing constraint on class override ([§14.7.6](#)) properties

An overriding property declaration shall specify the exact same accessibility modifiers and name as the inherited property, and there shall be an identity conversion ~~between the type of the overriding and the inherited property~~. If the inherited property has only a single accessor (i.e., if the inherited property is read-

only or write-only), the overriding property shall include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors.

is modified to

An overriding property declaration shall specify the exact same accessibility modifiers and name as the inherited property, and there shall be an identity conversion or (if the inherited property is read-only and has a value return - not a [ref return](#)) implicit reference conversion from the type of the overriding property to the type of the inherited property. If the inherited property has only a single accessor (i.e., if the inherited property is read-only or write-only), the overriding property shall include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors. **The overriding property's type must be at least as accessible as the overriding property** (Accessibility domains - [§7.5.3](#)).

The remainder of the draft specification below proposes a further extension to covariant returns of interface methods to be considered later.

Interface Method, Property, and Indexer Override

Adding to the kinds of members that are permitted in an interface with the addition of the DIM feature in C# 8.0, we further add support for `override` members along with covariant returns. These follow the rules of `override` members as specified for classes, with the following differences:

The following text in classes:

The method overridden by an override declaration is known as the ***overridden base method***. For an override method `M` declared in a class `C`, the overridden base method is determined by examining each base class of `C`, starting with the direct base class of `C` and continuing with each successive direct base class, until in a given base class type at least one accessible method is located which has the same signature as `M` after substitution of type arguments.

is given the corresponding specification for interfaces:

The method overridden by an override declaration is known as the ***overridden base method***. For an override method `M` declared in an interface `I`, the overridden base method is determined by examining each direct or indirect base interface of `I`, collecting the set of interfaces declaring an accessible method which has the same signature as `M` after substitution of type arguments. If this set of interfaces has a *most derived type*, to which there is an identity or implicit reference conversion from every type in this set, and that type contains a unique such method declaration, then that is the *overridden base method*.

We similarly permit `override` properties and indexers in interfaces as specified for classes in *15.7.6 Virtual, sealed, override, and abstract accessors*.

Name Lookup

Name lookup in the presence of class `override` declarations currently modify the result of name lookup by imposing on the found member details from the most derived `override` declaration in the class hierarchy starting from the type of the identifier's qualifier (or `this` when there is no qualifier). For example, in *12.6.2.2 Corresponding parameters* we have

For virtual methods and indexers defined in classes, the parameter list is picked from the first declaration or override of the function member found when starting with the static type of the receiver, and searching through its base classes.

to this we add

For virtual methods and indexers defined in interfaces, the parameter list is picked from the declaration or override of the function member found in the most derived type among those types containing the declaration of override of the function member. It is a compile-time error if no unique such type exists.

For the result type of a property or indexer access, the existing text

- If `I` identifies an instance property, then the result is a property access with an associated instance expression of `E` and an associated type that is the type of the property. If `T` is a class type, the associated type is picked from the first declaration or override of the property found when starting with `T`, and searching through its base classes.

is augmented with

If *T* is an interface type, the associated type is picked from the declaration or override of the property found in the most derived of *T* or its direct or indirect base interfaces. It is a compile-time error if no unique such type exists.

A similar change should be made in *12.7.7.3 Indexer access*

In *12.7.6 Invocation expressions* we augment the existing text

- Otherwise, the result is a value, with an associated type of the return type of the method or delegate. If the invocation is of an instance method, and the receiver is of a class type *T*, the associated type is picked from the first declaration or override of the method found when starting with *T* and searching through its base classes.

with

If the invocation is of an instance method, and the receiver is of an interface type *T*, the associated type is picked from the declaration or override of the method found in the most derived interface from among *T* and its direct and indirect base interfaces. It is a compile-time error if no unique such type exists.

Implicit Interface Implementations

This section of the specification

For purposes of interface mapping, a class member *A* matches an interface member *B* when:

- *A* and *B* are methods, and the name, type, and formal parameter lists of *A* and *B* are identical.
- *A* and *B* are properties, the name and type of *A* and *B* are identical, and *A* has the same accessors as *B* (*A* is permitted to have additional accessors if it is not an explicit interface member implementation).
- *A* and *B* are events, and the name and type of *A* and *B* are identical.
- *A* and *B* are indexers, the type and formal parameter lists of *A* and *B* are identical, and *A* has the same accessors as *B* (*A* is permitted to have additional accessors if it is not an explicit interface member implementation).

is modified as follows:

For purposes of interface mapping, a class member **A** matches an interface member **B** when:

- **A** and **B** are methods, and the name and formal parameter lists of **A** and **B** are identical, and the return type of **A** is convertible to the return type of **B** via an identity of implicit reference conversion to the return type of **B**.
- **A** and **B** are properties, the name of **A** and **B** are identical, **A** has the same accessors as **B** (**A** is permitted to have additional accessors if it is not an explicit interface member implementation), and the type of **A** is convertible to the return type of **B** via an identity conversion or, if **A** is a readonly property, an implicit reference conversion.
- **A** and **B** are events, and the name and type of **A** and **B** are identical.
- **A** and **B** are indexers, the formal parameter lists of **A** and **B** are identical, **A** has the same accessors as **B** (**A** is permitted to have additional accessors if it is not an explicit interface member implementation), and the type of **A** is convertible to the return type of **B** via an identity conversion or, if **A** is a readonly indexer, an implicit reference conversion.

This is technically a breaking change, as the program below prints "C1.M" today, but would print "C2.M" under the proposed revision.

```
c#  
  
using System;  
  
interface I1 { object M(); }  
class C1 : I1 { public object M() { return "C1.M"; } }  
class C2 : C1, I1 { public new string M() { return "C2.M"; } }  
class Program  
{  
    static void Main()  
    {  
        I1 i = new C2();  
        Console.WriteLine(i.M());  
    }  
}
```

Due to this breaking change, we might consider not supporting covariant return types on implicit implementations.

Constraints on Interface Implementation

We will need a rule that an explicit interface implementation must declare a return type no less derived than the return type declared in any override in its base interfaces.

API Compatibility Implications

TBD

Open Issues

The specification does not say how the caller gets the more refined return type. Presumably that would be done in a way similar to the way that callers get the most derived override's parameter specifications.

If we have the following interfaces:

```
C#  
  
interface I1 { I1 M(); }  
interface I2 { I2 M(); }  
interface I3: I1, I2 { override I3 M(); }
```

Note that in `I3`, the methods `I1.M()` and `I2.M()` have been “merged”. When implementing `I3`, it is necessary to implement them both together.

Generally, we require an explicit implementation to refer to the original method. The question is, in a class

```
C#  
  
class C : I1, I2, I3  
{  
    C IN.M();  
}
```

What does that mean here? What should `N` be?

I suggest that we permit implementing either `I1.M` or `I2.M` (but not both), and treat that as an implementation of both.

Drawbacks

- [] Every language change must pay for itself.

- [] We should ensure that the performance is reasonable, even in the case of deep inheritance hierarchies
- [] We should ensure that artifacts of the translation strategy do not affect language semantics, even when consuming new IL from old compilers.

Alternatives

We could relax the language rules slightly to allow, in source,

```
C#  
  
abstract class Cloneable  
{  
    public abstract Cloneable Clone();  
}  
  
class Digit : Cloneable  
{  
    public override Cloneable Clone()  
    {  
        return this.Clone();  
    }  
  
    public new Digit Clone() // Error: 'Digit' already defines a member  
    called 'Clone' with the same parameter types  
    {  
        return this;  
    }  
}
```

Unresolved questions

- [] How will APIs that have been compiled to use this feature work in older versions of the language?

Design meetings

- some discussion at <https://github.com/dotnet/roslyn/issues/357>.
- <https://github.com/dotnet/csharplang/blob/master/meetings/2020/LDM-2020-01-08.md>
- Offline discussion toward a decision to support overriding of class methods only in C# 9.0.

Extension `GetEnumerator` support for `foreach` loops.

Article • 2022-02-23 • 5 minutes to read

Summary

Allow `foreach` loops to recognize an extension method `GetEnumerator` method that otherwise satisfies the `foreach` pattern, and loop over the expression when it would otherwise be an error.

Motivation

This will bring `foreach` inline with how other features in C# are implemented, including `async` and pattern-based deconstruction.

Detailed design

The spec change is relatively straightforward. We modify `The foreach statement` section to this text:

The compile-time processing of a `foreach` statement first determines the *collection type*, *enumerator type* and *element type* of the expression. This determination proceeds as follows:

- If the type `X` of *expression* is an array type then there is an implicit reference conversion from `X` to the `IEnumerable` interface (since `System.Array` implements this interface). The *collection type* is the `IEnumerable` interface, the *enumerator type* is the `IEnumerator` interface and the *element type* is the element type of the array type `X`.
- If the type `X` of *expression* is `dynamic` then there is an implicit conversion from *expression* to the `IEnumerable` interface ([§10.2.10](#)). The *collection type* is the `IEnumerable` interface and the *enumerator type* is the `IEnumerator` interface. If the `var` identifier is given as the *local_variable_type* then the *element type* is `dynamic`, otherwise it is `object`.
- Otherwise, determine whether the type `X` has an appropriate `GetEnumerator` method:

- Perform member lookup on the type `X` with identifier `GetEnumerator` and no type arguments. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match that is not a method group, check for an enumerable interface as described below. It is recommended that a warning be issued if member lookup produces anything except a method group or no match.
- Perform overload resolution using the resulting method group and an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, check for an enumerable interface as described below. It is recommended that a warning be issued if overload resolution produces anything except an unambiguous public instance method or no applicable methods.
- If the return type `E` of the `GetEnumerator` method is not a class, struct or interface type, an error is produced and no further steps are taken.
- Member lookup is performed on `E` with the identifier `Current` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.
- Member lookup is performed on `E` with the identifier `MoveNext` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.
- Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not `bool`, an error is produced and no further steps are taken.
- The **collection type** is `X`, the **enumerator type** is `E`, and the **element type** is the type of the `Current` property.
- Otherwise, check for an enumerable interface:
 - If among all the types `Ti` for which there is an implicit conversion from `X` to `IEnumerable<Ti>`, there is a unique type `T` such that `T` is not `dynamic` and for all the other `Ti` there is an implicit conversion from `IEnumerable<T>` to `IEnumerable<Ti>`, then the **collection type** is the interface `IEnumerable<T>`, the **enumerator type** is the interface `IEnumerator<T>`, and the **element type** is `T`.
 - Otherwise, if there is more than one such type `T`, then an error is produced and no further steps are taken.

- Otherwise, if there is an implicit conversion from `X` to the `System.Collections.IEnumerable` interface, then the **collection type** is this interface, the **enumerator type** is the interface `System.Collections.IEnumerator`, and the **element type** is `object`.
- Otherwise, determine whether the type 'X' has an appropriate `GetEnumerator` extension method:
 - Perform extension method lookup on the type `X` with identifier `GetEnumerator`. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match which is not a method group, an error is produced and no further steps are taken. It is recommended that a warning be issued if member lookup produces anything except a method group or no match.
 - Perform overload resolution using the resulting method group and a single argument of type `X`. If overload resolution produces no applicable methods, results in an ambiguity, or results in a single best method but that method is not accessible, an error is produced and no further steps are taken.
 - This resolution permits the first argument to be passed by ref if `X` is a struct type, and the ref kind is `in`.
 - If the return type `E` of the `GetEnumerator` method is not a class, struct or interface type, an error is produced and no further steps are taken.
 - Member lookup is performed on `E` with the identifier `Current` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.
 - Member lookup is performed on `E` with the identifier `MoveNext` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.
 - Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not `bool`, an error is produced and no further steps are taken.
 - The **collection type** is `X`, the **enumerator type** is `E`, and the **element type** is the type of the `Current` property.
- Otherwise, an error is produced and no further steps are taken.

For `await foreach`, the rules are similarly modified. The only change that is required to that spec is removing the `Extension methods do not contribute.` line from the description, as the rest of that spec is based on the above rules with different names substituted for the pattern methods.

Drawbacks

Every change adds additional complexity to the language, and this potentially allows things that weren't designed to be `foreached` to be `foreached`, like `Range`.

Alternatives

Doing nothing.

Unresolved questions

None at this point.

Lambda discard parameters

Article • 2022-02-23 • 2 minutes to read

Summary

Allow discards (`_`) to be used as parameters of lambdas and anonymous methods. For example:

- lambdas: `(_, _) => 0, (int _, int _) => 0`
- anonymous methods: `delegate(int _, int _) { return 0; }`

Motivation

Unused parameters do not need to be named. The intent of discards is clear, i.e. they are unused/discarded.

Detailed design

Method parameters - [§14.6.2](#) In the parameter list of a lambda or anonymous method with more than one parameter named `_`, such parameters are discard parameters. Note: if a single parameter is named `_` then it is a regular parameter for backwards compatibility reasons.

Discard parameters do not introduce any names to any scopes. Note this implies they do not cause any `_` (underscore) names to be hidden.

Simple names ([§11.7.4](#)) If `k` is zero and the *simple_name* appears within a *block* and if the *block*'s (or an enclosing *block*'s) local variable declaration space (Declarations - [§7.3](#)) contains a local variable, parameter (with the exception of discard parameters) or constant with name `I`, then the *simple_name* refers to that local variable, parameter or constant and is classified as a variable or value.

Scopes - [§7.7](#) With the exception of discard parameters, the scope of a parameter declared in a *lambda_expression* ([§11.16](#)) is the *anonymous_function_body* of that *lambda_expression* With the exception of discard parameters, the scope of a parameter declared in an *anonymous_method_expression* ([§11.16](#)) is the *block* of that *anonymous_method_expression*.

Related spec sections

- Corresponding parameters - [§11.6.2.2](#) 

Attributes on local functions

Article • 2022-02-23 • 2 minutes to read

Attributes

Local function declarations are now permitted to have attributes ([§21](#)). Parameters and type parameters on local functions are also allowed to have attributes.

Attributes with a specified meaning when applied to a method, its parameters, or its type parameters will have the same meaning when applied to a local function, its parameters, or its type parameters, respectively.

A local function can be made conditional in the same sense as a conditional method ([§21.5.3](#)) by decorating it with a `[ConditionalAttribute]`. A conditional local function must also be `static`. All restrictions on conditional methods also apply to conditional local functions, including that the return type must be `void`.

Extern

The `extern` modifier is now permitted on local functions. This makes the local function external in the same sense as an external method ([§14.6.8](#)).

Similarly to an external method, the *local-function-body* of an external local function must be a semicolon. A semicolon *local-function-body* is only permitted on an external local function.

An external local function must also be `static`.

Syntax

The [local functions grammar](#) is modified as follows:

```
local-function-header
  : attributes? local-function-modifiers? return-type identifier type-
  parameter-list?
    ( formal-parameter-list? ) type-parameter-constraints-clauses
  ;

local-function-modifiers
  : ( async | unsafe | static | extern)*
```

;

local-function-body

| arrow-expression-body

| ';'

;

Native-sized integers

Article • 2022-07-22 • 12 minutes to read

Summary

Language support for a native-sized signed and unsigned integer types.

The motivation is for interop scenarios and for low-level libraries.

Design

The identifiers `nint` and `nuint` are new contextual keywords that represent native signed and unsigned integer types. The identifiers are only treated as keywords when name lookup does not find a viable result at that program location.

```
C#
```

```
nint x = 3;
string y = nameof(nuint);
_ = nint.Equals(x, 3);
```

The types `nint` and `nuint` are represented by the underlying types `System.IntPtr` and `System.UIntPtr` with compiler surfacing additional conversions and operations for those types as native ints.

Constants

Constant expressions may be of type `nint` or `nuint`. There is no direct syntax for native int literals. Implicit or explicit casts of other integral constant values can be used instead:

```
const nint i = (nint)42;
```

`nint` constants are in the range [`int.MinValue`, `int.MaxValue`].

`nuint` constants are in the range [`uint.MinValue`, `uint.MaxValue`].

There are no `MinValue` or `MaxValue` fields on `nint` or `nuint` because, other than `nuint.MinValue`, those values cannot be emitted as constants.

Constant folding is supported for all unary operators { `+`, `-`, `~` } and binary operators { `+`, `-`, `*`, `/`, `%`, `==`, `!=`, `<`, `<=`, `>`, `>=`, `&`, `|`, `^`, `<<`, `>>` }. Constant folding operations are

evaluated with `Int32` and `UInt32` operands rather than native ints for consistent behavior regardless of compiler platform. If the operation results in a constant value in 32-bits, constant folding is performed at compile-time. Otherwise the operation is executed at runtime and not considered a constant.

Conversions

There is an identity conversion between `nint` and `IntPtr`, and between `nuint` and `UIntPtr`. There is an identity conversion between compound types that differ by native ints and underlying types only: arrays, `Nullable<>`, constructed types, and tuples.

The tables below cover the conversions between special types. (The IL for each conversion includes the variants for `unchecked` and `checked` contexts if different.)

General notes on the table below:

- `conv.u` is a zero-extending conversion to native integer and `conv.i` is sign-extending conversion to native integer.
- `checked` contexts for both **widening** and **narrowing** are:
 - `conv.ovf.*` for `signed to *`
 - `conv.ovf.*.un` for `unsigned to *`
- `unchecked` contexts for **widening** are:
 - `conv.i*` for `signed to *` (where `*` is the target width)
 - `conv.u*` for `unsigned to *` (where `*` is the target width)
- `unchecked` contexts for **narrowing** are:
 - `conv.i*` for `any to signed *` (where `*` is the target width)
 - `conv.u*` for `any to unsigned *` (where `*` is the target width)

Taking a few examples:

- `sbyte to nint` and `sbyte to nuint` use `conv.i` while `byte to nint` and `byte to nuint` use `conv.u` because they are all **widening**.
 - `nint to byte` and `nuint to byte` use `conv.u1` while `nint to sbyte` and `nuint to sbyte` use `conv.i1`. For `byte`, `sbyte`, `short`, and `ushort` the "stack type" is `int32`. So `conv.i1` is effectively "downcast to a signed byte and then sign-extend up to `int32`" while `conv.u1` is effectively "downcast to an unsigned byte and then zero-extend up to `int32`".
 - `checked void* to nint` uses `conv.ovf.i.un` the same way that `checked void* to long` uses `conv.ovf.i8.un`.

Conversion from A to Nullable is:

- an implicit nullable conversion if there is an identity conversion or implicit conversion from `A` to `B`;
- an explicit nullable conversion if there is an explicit conversion from `A` to `B`;
- otherwise invalid.

Conversion from `Nullable<A>` to `B` is:

- an explicit nullable conversion if there is an identity conversion or implicit or explicit numeric conversion from `A` to `B`;
- otherwise invalid.

Conversion from `Nullable<A>` to `Nullable` is:

- an identity conversion if there is an identity conversion from `A` to `B`;
- an explicit nullable conversion if there is an implicit or explicit numeric conversion from `A` to `B`;
- otherwise invalid.

Operators

The predefined operators are as follows. These operators are considered during overload resolution based on normal rules for implicit conversions *if at least one of the operands is of type `nint` or `nuint`*.

(The IL for each operator includes the variants for `unchecked` and `checked` contexts if different.)

Unary	Operator Signature	IL
<code>+</code>	<code>nint operator +(nint value)</code>	<code>nop</code>
<code>+</code>	<code>nuint operator +(nuint value)</code>	<code>nop</code>
<code>-</code>	<code>nint operator -(nint value)</code>	<code>neg</code>
<code>~</code>	<code>nint operator ~(nint value)</code>	<code>not</code>
<code>~</code>	<code>nuint operator ~(nuint value)</code>	<code>not</code>

Binary	Operator Signature	IL
<code>+</code>	<code>nint operator +(nint left, nint right)</code>	<code>add / add.ovf</code>
<code>+</code>	<code>nuint operator +(nuint left, nuint right)</code>	<code>add / add.ovf.un</code>

Binary	Operator Signature	IL
-	nint operator -(nint left, nint right)	sub / sub.ovf
-	nuint operator -(nuint left, nuint right)	sub / sub.ovf.un
*	nint operator *(nint left, nint right)	mul / mul.ovf
*	nuint operator *(nuint left, nuint right)	mul / mul.ovf.un
/	nint operator /(nint left, nint right)	div
/	nuint operator /(nuint left, nuint right)	div.un
%	nint operator %(nint left, nint right)	rem
%	nuint operator %(nuint left, nuint right)	rem.un
==	bool operator ==(nint left, nint right)	beq / ceq
==	bool operator ==(nuint left, nuint right)	beq / ceq
!=	bool operator !=(nint left, nint right)	bne
!=	bool operator !=(nuint left, nuint right)	bne
<	bool operator <(nint left, nint right)	blt / clt
<	bool operator <(nuint left, nuint right)	blt.un / clt.un
<=	bool operator <=(nint left, nint right)	ble
<=	bool operator <=(nuint left, nuint right)	ble.un
>	bool operator >(nint left, nint right)	bgt / cgt
>	bool operator >(nuint left, nuint right)	bgt.un / cgt.un
>=	bool operator >=(nint left, nint right)	bge
>=	bool operator >=(nuint left, nuint right)	bge.un
&	nint operator &(amp;nint left, nint right)	and
&	nuint operator &(amp;nuint left, nuint right)	and
	nint operator (nint left, nint right)	or
	nuint operator (nuint left, nuint right)	or
^	nint operator ^(nint left, nint right)	xor

Binary	Operator Signature	IL
<code>^</code>	<code>nuint operator ^(nuint left, nuint right)</code>	<code>xor</code>
<code><<</code>	<code>nint operator <<(nint left, int right)</code>	<code>shl</code>
<code><<</code>	<code>nuint operator <<(nuint left, int right)</code>	<code>shl</code>
<code>>></code>	<code>nint operator >>(nint left, int right)</code>	<code>shr</code>
<code>>></code>	<code>nuint operator >>(nuint left, int right)</code>	<code>shr.un</code>

For some binary operators, the IL operators support additional operand types (see [ECMA-335](#) III.1.5 Operand type table). But the set of operand types supported by C# is limited for simplicity and for consistency with existing operators in the language.

Lifted versions of the operators, where the arguments and return types are `nint?` and `nuint?`, are supported.

Compound assignment operations `x op= y` where `x` or `y` are native ints follow the same rules as with other primitive types with pre-defined operators. Specifically the expression is bound as `x = (T)(x op y)` where `T` is the type of `x` and where `x` is only evaluated once.

The shift operators should mask the number of bits to shift - to 5 bits if `sizeof(nint)` is 4, and to 6 bits if `sizeof(nint)` is 8. (see [§11.10](#)) in C# spec).

The C#9 compiler will report errors binding to predefined native integer operators when compiling with an earlier language version, but will allow use of predefined conversions to and from native integers.

```
csc -langversion:9 -t:library A.cs
```

C#

```
public class A
{
    public static nint F;
}
```

```
csc -langversion:8 -r:A.dll B.cs
```

C#

```
class B : A
{
```

```

static void Main()
{
    F = F + 1; // error: nint operator+ not available with -
langversion:8
    F = (System.IntPtr)F + 1; // ok
}
}

```

Pointer arithmetic

There are no predefined operators in C# for pointer addition or subtraction with native integer offsets. Instead, `nint` and `nuint` values are promoted to `long` and `ulong` and pointer arithmetic uses predefined operators for those types.

C#

```

static T* AddLeftS(nint x, T* y) => x + y; // T* operator +(long left, T*
right)
static T* AddLeftU(nuint x, T* y) => x + y; // T* operator +(ulong left, T*
right)
static T* AddRightS(T* x, nint y) => x + y; // T* operator +(T* left, long
right)
static T* AddRightU(T* x, nuint y) => x + y; // T* operator +(T* left, ulong
right)
static T* SubRightS(T* x, nint y) => x - y; // T* operator -(T* left, long
right)
static T* SubRightU(T* x, nuint y) => x - y; // T* operator -(T* left, ulong
right)

```

Binary numeric promotions

The *binary numeric promotions* informative text (see [§11.4.7.3](#)) in C# spec) is updated as follows:

- ...
- Otherwise, if either operand is of type `ulong`, the other operand is converted to type `ulong`, or a binding-time error occurs if the other operand is of type `sbyte`, `short`, `int`, `nint`, or `long`.
- Otherwise, if either operand is of type `nuint`, the other operand is converted to type `nuint`, or a binding-time error occurs if the other operand is of type `sbyte`, `short`, `int`, `nint`, or `long`.
- Otherwise, if either operand is of type `long`, the other operand is converted to type `long`.

- Otherwise, if either operand is of type `uint` and the other operand is of type `sbyte`, `short`, `nint`, or `int`, both operands are converted to type `long`.
- Otherwise, if either operand is of type `uint`, the other operand is converted to type `uint`.
- **Otherwise, if either operand is of type `nint`, the other operand is converted to type `nint`.**
- Otherwise, both operands are converted to type `int`.

Dynamic

The conversions and operators are synthesized by the compiler and are not part of the underlying `IntPtr` and `UIntPtr` types. As a result those conversions and operators *are not available* from the runtime binder for `dynamic`.

C#

```
nint x = 2;
nint y = x + x; // ok
dynamic d = x;
nint z = d + x; // RuntimeBinderException: '+' cannot be applied
'System.IntPtr' and 'System.IntPtr'
```

Type members

The only constructor for `nint` or `nuint` is the parameter-less constructor.

The following members of `System.IntPtr` and `System.UIntPtr` *are explicitly excluded* from `nint` or `nuint`:

C#

```
// constructors
// arithmetic operators
// implicit and explicit conversions
public static readonly IntPtr Zero; // use 0 instead
public static int Size { get; } // use sizeof() instead
public static IntPtr Add(IntPtr pointer, int offset);
public static IntPtr Subtract(IntPtr pointer, int offset);
public int.ToInt32();
public long.ToInt64();
public void* ToPointer();
```

The remaining members of `System.IntPtr` and `System.UIntPtr` are implicitly included in `nint` and `nuint`. For .NET Framework 4.7.2:

```
C#
```

```
public override bool Equals(object obj);
public override int GetHashCode();
public override string ToString();
public string ToString(string format);
```

Interfaces implemented by `System.IntPtr` and `System.UIntPtr` are implicitly included in `nint` and `nuint`, with occurrences of the underlying types replaced by the corresponding native integer types. For instance if `IntPtr` implements `ISerializable`, `IEquatable<IntPtr>`, `IComparable<IntPtr>`, then `nint` implements `ISerializable`, `IEquatable<nint>`, `IComparable<nint>`.

Overriding, hiding, and implementing

`nint` and `System.IntPtr`, and `nuint` and `System.UIntPtr`, are considered equivalent for overriding, hiding, and implementing.

Overloads cannot differ by `nint` and `System.IntPtr`, and `nuint` and `System.UIntPtr`, alone. Overrides and implementations may differ by `nint` and `System.IntPtr`, or `nuint` and `System.UIntPtr`, alone. Methods hide other methods that differ by `nint` and `System.IntPtr`, or `nuint` and `System.UIntPtr`, alone.

Miscellaneous

`nint` and `nuint` expressions used as array indices are emitted without conversion.

```
C#
```

```
static object GetItem(object[] array, nint index)
{
    return array[index]; // ok
}
```

`nint` and `nuint` cannot be used as an `enum` base type from C#.

```
C#
```

```
enum E : nint // error: byte, sbyte, short, ushort, int, uint, long, or
ulong expected
```

```
{  
}
```

Reads and writes are atomic for `nint` and `nuint`.

Fields may be marked `volatile` for types `nint` and `nuint`. [ECMA-334](#) 15.5.4 does not include `enum` with base type `System.IntPtr` or `System.UIntPtr` however.

`default(nint)` and `new nint()` are equivalent to `(nint)0`; `default(nuint)` and `new nuint()` are equivalent to `(nuint)0`.

`typeof(nint)` is `typeof(IntPtr)`; `typeof(nuint)` is `typeof(UIntPtr)`.

`sizeof(nint)` and `sizeof(nuint)` are supported but require compiling in an unsafe context (as required for `sizeof(IntPtr)` and `sizeof(UIntPtr)`). The values are not compile-time constants. `sizeof(nint)` is implemented as `sizeof(IntPtr)` rather than `IntPtr.Size`; `sizeof(nuint)` is implemented as `sizeof(UIntPtr)` rather than `UIntPtr.Size`.

Compiler diagnostics for type references involving `nint` or `nuint` report `nint` or `nuint` rather than `IntPtr` or `UIntPtr`.

Metadata

`nint` and `nuint` are represented in metadata as `System.IntPtr` and `System.UIntPtr`.

Type references that include `nint` or `nuint` are emitted with a `System.Runtime.CompilerServices.NativeIntegerAttribute` to indicate which parts of the type reference are native ints.

```
C#
```

```
namespace System.Runtime.CompilerServices  
{  
    [AttributeUsage(  
        AttributeTargets.Class |  
        AttributeTargets.Event |  
        AttributeTargets.Field |  
        AttributeTargets.GenericParameter |  
        AttributeTargets.Parameter |  
        AttributeTargets.Property |  
        AttributeTargets.ReturnValue,  
        AllowMultiple = false,  
        Inherited = false)]  
    public sealed class NativeIntegerAttribute : Attribute  
    {  
    }  
}
```

```

    public NativeIntegerAttribute()
    {
        TransformFlags = new[] { true };
    }
    public NativeIntegerAttribute(bool[] flags)
    {
        TransformFlags = flags;
    }
    public readonly bool[] TransformFlags;
}
}

```

The encoding of type references with `NativeIntegerAttribute` is covered in [NativeIntegerAttribute.md](#).

Alternatives

An alternative to the "type erasure" approach above is to introduce new types:

`System.NativeInt` and `System.NativeUInt`.

C#

```

public readonly struct NativeInt
{
    public IntPtr Value;
}

```

Distinct types would allow overloading distinct from `IntPtr` and would allow distinct parsing and `ToString()`. But there would be more work for the CLR to handle these types efficiently which defeats the primary purpose of the feature - efficiency. And interop with existing native int code that uses `IntPtr` would be more difficult.

Another alternative is to add more native int support for `IntPtr` in the framework but without any specific compiler support. Any new conversions and arithmetic operations would be supported by the compiler automatically. But the language would not provide keywords, constants, or `checked` operations.

Function Pointers

Article • 2022-03-24 • 22 minutes to read

Summary

This proposal provides language constructs that expose IL opcodes that cannot currently be accessed efficiently, or at all, in C# today: `ldftn` and `calli`. These IL opcodes can be important in high performance code and developers need an efficient way to access them.

Motivation

The motivations and background for this feature are described in the following issue (as is a potential implementation of the feature):

<https://github.com/dotnet/csharplang/issues/191> ↗

This is an alternate design proposal to [compiler intrinsics](#) ↗

Detailed Design

Function pointers

The language will allow for the declaration of function pointers using the `delegate*` syntax. The full syntax is described in detail in the next section but it is meant to resemble the syntax used by `Func` and `Action` type declarations.

C#

```
unsafe class Example {
    void Example(Action<int> a, delegate*<int, void> f) {
        a(42);
        f(42);
    }
}
```

These types are represented using the function pointer type as outlined in ECMA-335. This means invocation of a `delegate*` will use `calli` where invocation of a `delegate` will use `callvirt` on the `Invoke` method. Syntactically though invocation is identical for both constructs.

The ECMA-335 definition of method pointers includes the calling convention as part of the type signature (section 7.1). The default calling convention will be `managed`.

Unmanaged calling conventions can be specified by putting an `unmanaged` keyword after the `delegate*` syntax, which will use the runtime platform default. Specific unmanaged conventions can then be specified in brackets to the `unmanaged` keyword by specifying any type starting with `CallConv` in the `System.Runtime.CompilerServices` namespace, leaving off the `CallConv` prefix. These types must come from the program's core library, and the set of valid combinations is platform-dependent.

```
C#
```

```
//This method has a managed calling convention. This is the same as leaving
the managed keyword off.
delegate* managed<int, int>;

// This method will be invoked using whatever the default unmanaged calling
convention on the runtime
// platform is. This is platform and architecture dependent and is
determined by the CLR at runtime.
delegate* unmanaged<int, int>;

// This method will be invoked using the cdecl calling convention
// Cdecl maps to System.Runtime.CompilerServices.CallConvCdecl
delegate* unmanaged[Cdecl] <int, int>;

// This method will be invoked using the stdcall calling convention, and
suppresses GC transition
// Stdcall maps to System.Runtime.CompilerServices.CallConvStdcall
// SuppressGCTransition maps to
System.Runtime.CompilerServices.CallConvSuppressGCTransition
delegate* unmanaged[Stdcall, SuppressGCTransition] <int, int>;
```

Conversions between `delegate*` types is done based on their signature including the calling convention.

```
C#
```

```
unsafe class Example {
    void Conversions() {
        delegate*<int, int, int> p1 = ...;
        delegate* managed<int, int, int> p2 = ...;
        delegate* unmanaged<int, int, int> p3 = ...;

        p1 = p2; // okay p1 and p2 have compatible signatures
        Console.WriteLine(p2 == p1); // True
        p2 = p3; // error: calling conventions are incompatible
    }
}
```

A `delegate*` type is a pointer type which means it has all of the capabilities and restrictions of a standard pointer type:

- Only valid in an `unsafe` context.
- Methods which contain a `delegate*` parameter or return type can only be called from an `unsafe` context.
- Cannot be converted to `object`.
- Cannot be used as a generic argument.
- Can implicitly convert `delegate*` to `void*`.
- Can explicitly convert from `void*` to `delegate*`.

Restrictions:

- Custom attributes cannot be applied to a `delegate*` or any of its elements.
- A `delegate*` parameter cannot be marked as `params`
- A `delegate*` type has all of the restrictions of a normal pointer type.
- Pointer arithmetic cannot be performed directly on function pointer types.

Function pointer syntax

The full function pointer syntax is represented by the following grammar:

```
antlr
```

```
pointer_type
```

```
: ...  
| funcptr_type  
;
```

```
funcptr_type
```

```
: 'delegate' '*' calling_convention_specifier? '<  
funcptr_parameter_list funcptr_return_type '>  
;
```

```
calling_convention_specifier
```

```
: 'managed'  
| 'unmanaged' ('[' unmanaged_calling_convention ']')?  
;
```

```
unmanaged_calling_convention
```

```
: 'Cdecl'  
| 'Stdcall'  
| 'Thiscall'  
| 'Fastcall'  
| identifier (',' identifier)*  
;
```

```

funcptr_parameter_list
    : (funcptr_parameter ',')*
    ;

funcptr_parameter
    : funcptr_parameter_modifier? type
    ;

funcptr_return_type
    : funcptr_return_modifier? return_type
    ;

funcptr_parameter_modifier
    : 'ref'
    | 'out'
    | 'in'
    ;

funcptr_return_modifier
    : 'ref'
    | 'ref readonly'
    ;

```

If no `calling_convention_specifier` is provided, the default is `managed`. The precise metadata encoding of the `calling_convention_specifier` and what `identifiers` are valid in the `unmanaged_calling_convention` is covered in [Metadata Representation of Calling Conventions](#).

C#

```

delegate int Func1(string s);
delegate Func1 Func2(Func1 f);

// Function pointer equivalent without calling convention
delegate* <string, int>;
delegate* <delegate* <string, int>, delegate* <string, int>>;

// Function pointer equivalent with calling convention
delegate* managed <string, int>;
delegate* <delegate* managed <string, int>, delegate* <string, int>>;

```

Function pointer conversions

In an unsafe context, the set of available implicit conversions (Implicit conversions) is extended to include the following implicit pointer conversions:

- *Existing conversions* - ([§22.5](#))

- From *funcptr_type* F_0 to another *funcptr_type* F_1 , provided all of the following are true:
 - F_0 and F_1 have the same number of parameters, and each parameter D_{0n} in F_0 has the same `ref`, `out`, or `in` modifiers as the corresponding parameter D_{1n} in F_1 .
 - For each value parameter (a parameter with no `ref`, `out`, or `in` modifier), an identity conversion, implicit reference conversion, or implicit pointer conversion exists from the parameter type in F_0 to the corresponding parameter type in F_1 .
 - For each `ref`, `out`, or `in` parameter, the parameter type in F_0 is the same as the corresponding parameter type in F_1 .
 - If the return type is by value (no `ref` or `ref readonly`), an identity, implicit reference, or implicit pointer conversion exists from the return type of F_1 to the return type of F_0 .
 - If the return type is by reference (`ref` or `ref readonly`), the return type and `ref` modifiers of F_1 are the same as the return type and `ref` modifiers of F_0 .
 - The calling convention of F_0 is the same as the calling convention of F_1 .

Allow address-of to target methods

Method groups will now be allowed as arguments to an address-of expression. The type of such an expression will be a `delegate*` which has the equivalent signature of the target method and a managed calling convention:

```
C#
unsafe class Util {
    public static void Log() { }

    void Use() {
        delegate*<void> ptr1 = &Util.Log;

        // Error: type "delegate*<void>" not compatible with "delegate*
<int>";
        delegate*<int> ptr2 = &Util.Log;
    }
}
```

In an unsafe context, a method M is compatible with a function pointer type F if all of the following are true:

- `M` and `F` have the same number of parameters, and each parameter in `M` has the same `ref`, `out`, or `in` modifiers as the corresponding parameter in `F`.
- For each value parameter (a parameter with no `ref`, `out`, or `in` modifier), an identity conversion, implicit reference conversion, or implicit pointer conversion exists from the parameter type in `M` to the corresponding parameter type in `F`.
- For each `ref`, `out`, or `in` parameter, the parameter type in `M` is the same as the corresponding parameter type in `F`.
- If the return type is by value (no `ref` or `ref readonly`), an identity, implicit reference, or implicit pointer conversion exists from the return type of `F` to the return type of `M`.
- If the return type is by reference (`ref` or `ref readonly`), the return type and `ref` modifiers of `F` are the same as the return type and `ref` modifiers of `M`.
- The calling convention of `M` is the same as the calling convention of `F`. This includes both the calling convention bit, as well as any calling convention flags specified in the unmanaged identifier.
- `M` is a static method.

In an unsafe context, an implicit conversion exists from an address-of expression whose target is a method group `E` to a compatible function pointer type `F` if `E` contains at least one method that is applicable in its normal form to an argument list constructed by use of the parameter types and modifiers of `F`, as described in the following.

- A single method `M` is selected corresponding to a method invocation of the form `E(A)` with the following modifications:
 - The arguments list `A` is a list of expressions, each classified as a variable and with the type and modifier (`ref`, `out`, or `in`) of the corresponding *funcptr_parameter_list* of `F`.
 - The candidate methods are only those methods that are applicable in their normal form, not those applicable in their expanded form.
 - The candidate methods are only those methods that are static.
- If the algorithm of overload resolution produces an error, then a compile-time error occurs. Otherwise, the algorithm produces a single best method `M` having the same number of parameters as `F` and the conversion is considered to exist.
- The selected method `M` must be compatible (as defined above) with the function pointer type `F`. Otherwise, a compile-time error occurs.
- The result of the conversion is a function pointer of type `F`.

This means developers can depend on overload resolution rules to work in conjunction with the address-of operator:

C#

```
unsafe class Util {
    public static void Log() { }
    public static void Log(string p1) { }
    public static void Log(int i) { };

    void Use() {
        delegate*<void> a1 = &Log; // Log()
        delegate*<int, void> a2 = &Log; // Log(int i)

        // Error: ambiguous conversion from method group Log to "void*"
        void* v = &Log;
    }
}
```

The address-of operator will be implemented using the `&` instruction.

Restrictions of this feature:

- Only applies to methods marked as `static`.
- Non-`static` local functions cannot be used in `&`. The implementation details of these methods are deliberately not specified by the language. This includes whether they are static vs. instance or exactly what signature they are emitted with.

Operators on Function Pointer Types

The section in unsafe code on operators is modified as such:

In an unsafe context, several constructs are available for operating on all `_pointer_type_s` that are not `_funcptr_type_s`:

- The `*` operator may be used to perform pointer indirection ([§22.6.2](#)).
- The `->` operator may be used to access a member of a struct through a pointer ([§22.6.3](#)).
- The `[]` operator may be used to index a pointer ([§22.6.4](#)).
- The `&` operator may be used to obtain the address of a variable ([§22.6.5](#)).
- The `++` and `--` operators may be used to increment and decrement pointers ([§22.6.6](#)).
- The `+` and `-` operators may be used to perform pointer arithmetic ([§22.6.7](#)).
- The `==`, `!=`, `<`, `>`, `<=`, and `=>` operators may be used to compare pointers ([§22.6.8](#)).
- The `stackalloc` operator may be used to allocate memory from the call stack ([§22.8](#)).

- The `fixed` statement may be used to temporarily fix a variable so its address can be obtained ([§22.7](#)).

In an unsafe context, several constructs are available for operating on all `_funcptr_type_s`:

- The `&` operator may be used to obtain the address of static methods ([Allow address-of to target methods](#))
- The `==`, `!=`, `<`, `>`, `<=`, and `=>` operators may be used to compare pointers ([§22.6.8](#)).

Additionally, we modify all the sections in `Pointers in expressions` to forbid function pointer types, except `Pointer comparison` and `The sizeof operator`.

Better function member

The better function member specification will be changed to include the following line:

A `delegate*` is more specific than `void*`

This means that it is possible to overload on `void*` and a `delegate*` and still sensibly use the address-of operator.

Type Inference

In unsafe code, the following changes are made to the type inference algorithms:

Input types

[§11.6.3.4](#)

The following is added:

If `E` is an address-of method group and `T` is a function pointer type then all the parameter types of `T` are input types of `E` with type `T`.

Output types

[§11.6.3.5](#)

The following is added:

If E is an address-of method group and T is a function pointer type then the return type of T is an output type of E with type T .

Output type inferences

[§11.6.3.7](#)

The following bullet is added between bullets 2 and 3:

- If E is an address-of method group and T is a function pointer type with parameter types $T_1 \dots T_k$ and return type T_b , and overload resolution of E with the types $T_1 \dots T_k$ yields a single method with return type U , then a *lower-bound inference* is made from U to T_b .

Better conversion from expression

[§11.6.4.4](#)

The following sub-bullet is added as a case to bullet 2:

- V is a function pointer type `delegate*<V2..Vk, V1>` and U is a function pointer type `delegate*<U2..Uk, U1>`, and the calling convention of V is identical to U , and the refness of V_i is identical to U_i .

Lower-bound inferences

[§11.6.3.10](#)

The following case is added to bullet 3:

- V is a function pointer type `delegate*<V2..Vk, V1>` and there is a function pointer type `delegate*<U2..Uk, U1>` such that U is identical to `delegate*<U2..Uk, U1>`, and the calling convention of V is identical to U , and the refness of V_i is identical to U_i .

The first bullet of inference from U_i to V_i is modified to:

- If U is not a function pointer type and U_i is not known to be a reference type, or if U is a function pointer type and U_i is not known to be a function pointer type or a reference type, then an *exact inference* is made

Then, added after the 3rd bullet of inference from U_i to V_i :

- Otherwise, if V is `delegate*<V2..Vk, V1>` then inference depends on the i -th parameter of `delegate*<V2..Vk, V1>`:
 - If $V1$:
 - If the return is by value, then a *lower-bound inference* is made.
 - If the return is by reference, then an *exact inference* is made.
 - If $V2..Vk$:
 - If the parameter is by value, then an *upper-bound inference* is made.
 - If the parameter is by reference, then an *exact inference* is made.

Upper-bound inferences

[§11.6.3.11](#)

The following case is added to bullet 2:

- U is a function pointer type `delegate*<U2..Uk, U1>` and V is a function pointer type which is identical to `delegate*<V2..Vk, V1>`, and the calling convention of U is identical to V , and the refness of U_i is identical to V_i .

The first bullet of inference from U_i to V_i is modified to:

- If U is not a function pointer type and U_i is not known to be a reference type, or if U is a function pointer type and U_i is not known to be a function pointer type or a reference type, then an *exact inference* is made

Then added after the 3rd bullet of inference from U_i to V_i :

- Otherwise, if U is `delegate*<U2..Uk, U1>` then inference depends on the i -th parameter of `delegate*<U2..Uk, U1>`:
 - If $U1$:
 - If the return is by value, then an *upper-bound inference* is made.
 - If the return is by reference, then an *exact inference* is made.
 - If $U2..Uk$:
 - If the parameter is by value, then a *lower-bound inference* is made.
 - If the parameter is by reference, then an *exact inference* is made.

Metadata representation of `in`, `out`, and `ref readonly` parameters and return types

Function pointer signatures have no parameter flags location, so we must encode whether parameters and the return type are `in`, `out`, or `ref readonly` by using `modreqs`.

`in`

We reuse `System.Runtime.InteropServices.InAttribute`, applied as a `modreq` to the ref specifier on a parameter or return type, to mean the following:

- If applied to a parameter ref specifier, this parameter is treated as `in`.
- If applied to the return type ref specifier, the return type is treated as `ref readonly`.

`out`

We use `System.Runtime.InteropServices.OutAttribute`, applied as a `modreq` to the ref specifier on a parameter type, to mean that the parameter is an `out` parameter.

Errors

- It is an error to apply `OutAttribute` as a `modreq` to a return type.
- It is an error to apply both `InAttribute` and `OutAttribute` as a `modreq` to a parameter type.
- If either are specified via `modopt`, they are ignored.

Metadata Representation of Calling Conventions

Calling conventions are encoded in a method signature in metadata by a combination of the `CallKind` flag in the signature and zero or more `modopt`s at the start of the signature. ECMA-335 currently declares the following elements in the `CallKind` flag:

```
antlr
```

```
CallKind
  : default
  | unmanaged cdecl
  | unmanaged fastcall
  | unmanaged thiscall
```

```
| unmanaged stdcall  
| varargs  
;
```

Of these, function pointers in C# will support all but `varargs`.

In addition, the runtime (and eventually 335) will be updated to include a new `CallKind` on new platforms. This does not have a formal name currently, but this document will use `unmanaged ext` as a placeholder to stand for the new extensible calling convention format. With no `modopts`, `unmanaged ext` is the platform default calling convention, `unmanaged` without the square brackets.

Mapping the `calling_convention_specifier` to a `CallKind`

A `calling_convention_specifier` that is omitted, or specified as `managed`, maps to the default `CallKind`. This is default `CallKind` of any method not attributed with `UnmanagedCallersOnly`.

C# recognizes 4 special identifiers that map to specific existing unmanaged `CallKinds` from ECMA 335. In order for this mapping to occur, these identifiers must be specified on their own, with no other identifiers, and this requirement is encoded into the spec for `unmanaged_calling_conventions`. These identifiers are `Cdecl`, `Thiscall`, `Stdcall`, and `Fastcall`, which correspond to `unmanaged cdecl`, `unmanaged thiscall`, `unmanaged stdcall`, and `unmanaged fastcall`, respectively. If more than one `identifier` is specified, or the single `identifier` is not of the specially recognized identifiers, we perform special name lookup on the identifier with the following rules:

- We prepend the `identifier` with the string `CallConv`
- We look only at types defined in the `System.Runtime.CompilerServices` namespace.
- We look only at types defined in the core library of the application, which is the library that defines `System.Object` and has no dependencies.
- We look only at public types.

If lookup succeeds on all of the `identifiers` specified in an `unmanaged_calling_convention`, we encode the `CallKind` as `unmanaged ext`, and encode each of the resolved types in the set of `modopts` at the beginning of the function pointer signature. As a note, these rules mean that users cannot prefix these `identifiers` with `CallConv`, as that will result in looking up `CallConvCallConvVectorCall`.

When interpreting metadata, we first look at the `CallKind`. If it is anything other than `unmanaged ext`, we ignore all `modopts` on the return type for the purposes of

determining the calling convention, and use only the `CallKind`. If the `CallKind` is `unmanaged_ext`, we look at the `modopts` at the start of the function pointer type, taking the union of all types that meet the following requirements:

- The is defined in the core library, which is the library that references no other libraries and defines `System.Object`.
- The type is defined in the `System.Runtime.CompilerServices` namespace.
- The type starts with the prefix `CallConv`.
- The type is public.

These represent the types that must be found when performing lookup on the `identifiers` in an `unmanaged_calling_convention` when defining a function pointer type in source.

It is an error to attempt to use a function pointer with a `CallKind` of `unmanaged_ext` if the target runtime does not support the feature. This will be determined by looking for the presence of the `System.Runtime.CompilerServices.RuntimeFeature.UnmanagedCallKind` constant. If this constant is present, the runtime is considered to support the feature.

`System.Runtime.InteropServices.UnmanagedCallersOnlyAttribute`

`System.Runtime.InteropServices.UnmanagedCallersOnlyAttribute` is an attribute used by the CLR to indicate that a method should be called with a specific calling convention. Because of this, we introduce the following support for working with the attribute:

- It is an error to directly call a method annotated with this attribute from C#. Users must obtain a function pointer to the method and then invoke that pointer.
- It is an error to apply the attribute to anything other than an ordinary static method or ordinary static local function. The C# compiler will mark any non-static or static non-ordinary methods imported from metadata with this attribute as unsupported by the language.
- It is an error for a method marked with the attribute to have a parameter or return type that is not an `unmanaged_type`.
- It is an error for a method marked with the attribute to have type parameters, even if those type parameters are constrained to `unmanaged`.
- It is an error for a method in a generic type to be marked with the attribute.
- It is an error to convert a method marked with the attribute to a delegate type.
- It is an error to specify any types for `UnmanagedCallersOnly.CallConvs` that do not meet the requirements for calling convention `modopts` in metadata.

When determining the calling convention of a method marked with a valid `UnmanagedCallersOnly` attribute, the compiler performs the following checks on the types specified in the `CallConvs` property to determine the effective `CallKind` and `modopts` that should be used to determine the calling convention:

- If no types are specified, the `CallKind` is treated as `unmanaged ext`, with no calling convention `modopts` at the start of the function pointer type.
- If there is one type specified, and that type is named `CallConvCdecl`, `CallConvThiscall`, `CallConvStdcall`, or `CallConvFastcall`, the `CallKind` is treated as `unmanaged cdecl`, `unmanaged thiscall`, `unmanaged stdcall`, or `unmanaged fastcall`, respectively, with no calling convention `modopts` at the start of the function pointer type.
- If multiple types are specified or the single type is not named one of the specially called out types above, the `CallKind` is treated as `unmanaged ext`, with the union of the types specified treated as `modopts` at the start of the function pointer type.

The compiler then looks at this effective `CallKind` and `modopt` collection and uses normal metadata rules to determine the final calling convention of the function pointer type.

Open Questions

Detecting runtime support for `unmanaged ext`

<https://github.com/dotnet/runtime/issues/38135> tracks adding this flag. Depending on the feedback from review, we will either use the property specified in the issue, or use the presence of `UnmanagedCallersOnlyAttribute` as the flag that determines whether the runtime supports `unmanaged ext`.

Considerations

Allow instance methods

The proposal could be extended to support instance methods by taking advantage of the `EXPLICITTHIS` CLI calling convention (named `instance` in C# code). This form of CLI function pointers puts the `this` parameter as an explicit first parameter of the function pointer syntax.

```

unsafe class Instance {
    void Use() {
        delegate* instance<Instance, string> f = &ToString;
        f(this);
    }
}

```

This is sound but adds some complication to the proposal. Particularly because function pointers which differed by the calling convention `instance` and `managed` would be incompatible even though both cases are used to invoke managed methods with the same C# signature. Also in every case considered where this would be valuable to have there was a simple work around: use a `static` local function.

C#

```

unsafe class Instance {
    void Use() {
        static string toString(Instance i) => i.ToString();
        delegate*<Instance, string> f = &toString;
        f(this);
    }
}

```

Don't require unsafe at declaration

Instead of requiring `unsafe` at every use of a `delegate*`, only require it at the point where a method group is converted to a `delegate*`. This is where the core safety issues come into play (knowing that the containing assembly cannot be unloaded while the value is alive). Requiring `unsafe` on the other locations can be seen as excessive.

This is how the design was originally intended. But the resulting language rules felt very awkward. It's impossible to hide the fact that this is a pointer value and it kept peeking through even without the `unsafe` keyword. For example the conversion to `object` can't be allowed, it can't be a member of a `class`, etc ... The C# design is to require `unsafe` for all pointer uses and hence this design follows that.

Developers will still be capable of presenting a *safe* wrapper on top of `delegate*` values the same way that they do for normal pointer types today. Consider:

C#

```

unsafe struct Action {
    delegate*<void> _ptr;
}

```

```
Action(delegate*<void> ptr) => _ptr = ptr;
public void Invoke() => _ptr();
}
```

Using delegates

Instead of using a new syntax element, `delegate*`, simply use existing `delegate` types with a `*` following the type:

C#

```
Func<object, object, bool>* ptr = &object.ReferenceEquals;
```

Handling calling convention can be done by annotating the `delegate` types with an attribute that specifies a `CallingConvention` value. The lack of an attribute would signify the managed calling convention.

Encoding this in IL is problematic. The underlying value needs to be represented as a pointer yet it also must:

1. Have a unique type to allow for overloads with different function pointer types.
2. Be equivalent for OHI purposes across assembly boundaries.

The last point is particularly problematic. This means that every assembly which uses `Func<int>*` must encode an equivalent type in metadata even though `Func<int>*` is defined in an assembly though don't control. Additionally any other type which is defined with the name `System.Func<T>` in an assembly that is not `mscorlib` must be different than the version defined in `mscorlib`.

One option that was explored was emitting such a pointer as `mod_req(Func<int>) void*`. This doesn't work though as a `mod_req` cannot bind to a `TypeSpec` and hence cannot target generic instantiations.

Named function pointers

The function pointer syntax can be cumbersome, particularly in complex cases like nested function pointers. Rather than have developers type out the signature every time the language could allow for named declarations of function pointers as is done with `delegate`.

C#

```
func* void Action();

unsafe class NamedExample {
    void M(Action a) {
        a();
    }
}
```

Part of the problem here is the underlying CLI primitive doesn't have names hence this would be purely a C# invention and require a bit of metadata work to enable. That is doable but is a significant amount of work. It essentially requires C# to have a companion to the type def table purely for these names.

Also when the arguments for named function pointers were examined we found they could apply equally well to a number of other scenarios. For example it would be just as convenient to declare named tuples to reduce the need to type out the full signature in all cases.

```
C#

(int x, int y) Point;

class NamedTupleExample {
    void M(Point p) {
        Console.WriteLine(p.x);
    }
}
```

After discussion we decided to not allow named declaration of `delegate*` types. If we find there is significant need for this based on customer usage feedback then we will investigate a naming solution that works for function pointers, tuples, generics, etc ... This is likely to be similar in form to other suggestions like full `typedef` support in the language.

Future Considerations

static delegates

This refers to [the proposal](#) to allow for the declaration of `delegate` types which can only refer to `static` members. The advantage being that such `delegate` instances can be allocation free and better in performance sensitive scenarios.

If the function pointer feature is implemented the `static delegate` proposal will likely be closed out. The proposed advantage of that feature is the allocation free nature. However recent investigations have found that is not possible to achieve due to assembly unloading. There must be a strong handle from the `static delegate` to the method it refers to in order to keep the assembly from being unloaded out from under it.

To maintain every `static delegate` instance would be required to allocate a new handle which runs counter to the goals of the proposal. There were some designs where the allocation could be amortized to a single allocation per call-site but that was a bit complex and didn't seem worth the trade off.

That means developers essentially have to decide between the following trade offs:

1. Safety in the face of assembly unloading: this requires allocations and hence `delegate` is already a sufficient option.
2. No safety in face of assembly unloading: use a `delegate*`. This can be wrapped in a `struct` to allow usage outside an `unsafe` context in the rest of the code.

Suppress emitting of `localsinit` flag.

Article • 2021-09-21 • 3 minutes to read

Summary

Allow suppressing emit of `localsinit` flag via `SkipLocalsInitAttribute` attribute.

Motivation

Background

Per CLR spec local variables that do not contain references are not initialized to a particular value by the VM/JIT. Reading from such variables without initialization is type-safe, but otherwise the behavior is undefined and implementation specific. Typically uninitialized locals contain whatever values were left in the memory that is now occupied by the stack frame. That could lead to nondeterministic behavior and hard to reproduce bugs.

There are two ways to "assign" a local variable:

- by storing a value or
- by specifying `localsinit` flag which forces everything that is allocated from the local memory pool to be zero-initialized NOTE: this includes both local variables and `stackalloc` data.

Use of uninitialized data is discouraged and is not allowed in verifiable code. While it might be possible to prove that by the means of flow analysis, it is permitted for the verification algorithm to be conservative and simply require that `localsinit` is set.

Historically C# compiler emits `localsinit` flag on all methods that declare locals.

While C# employs definite-assignment analysis which is more strict than what CLR spec would require (C# also needs to consider scoping of locals), it is not strictly guaranteed that the resulting code would be formally verifiable:

- CLR and C# rules may not agree on whether passing a local as `out` argument is a `use`.
- CLR and C# rules may not agree on treatment of conditional branches when conditions are known (constant propagation).
- CLR could as well simply require `localinits`, since that is permitted.

Problem

In high-performance application the cost of forced zero-initialization could be noticeable. It is particularly noticeable when `stackalloc` is used.

In some cases JIT can elide initial zero-initialization of individual locals when such initialization is "killed" by subsequent assignments. Not all JITs do this and such optimization has limits. It does not help with `stackalloc`.

To illustrate that the problem is real - there is a known bug where a method not containing any `IL` locals would not have `localsinit` flag. The bug is already being exploited by users by putting `stackalloc` into such methods - intentionally to avoid initialization costs. That is despite the fact that absence of `IL` locals is an unstable metric and may vary depending on changes in codegen strategy. The bug should be fixed and users should get a more documented and reliable way of suppressing the flag.

Detailed design

Allow specifying `System.Runtime.CompilerServices.SkipLocalsInitAttribute` as a way to tell the compiler to not emit `localsinit` flag.

The end result of this will be that the locals may not be zero-initialized by the JIT, which is in most cases unobservable in C#.

In addition to that `stackalloc` data will not be zero-initialized. That is definitely observable, but also is the most motivating scenario.

Permitted and recognized attribute targets are: `Method`, `Property`, `Module`, `Class`, `Struct`, `Interface`, `Constructor`. However compiler will not require that attribute is defined with the listed targets nor it will care in which assembly the attribute is defined.

When attribute is specified on a container (`class`, `module`, containing method for a nested method, ...), the flag affects all methods contained within the container.

Synthesized methods "inherit" the flag from the logical container/owner.

The flag affects only codegen strategy for actual method bodies. I.E. the flag has no effect on abstract methods and is not propagated to overriding/implementing methods.

This is explicitly a **compiler feature** and **not a language feature**.

Similarly to compiler command line switches the feature controls implementation details of a particular codegen strategy and does not need to be required by the C# spec.

Drawbacks

- Old/other compilers may not honor the attribute. Ignoring the attribute is compatible behavior. Only may result in a slight perf hit.
- The code without `localinits` flag may trigger verification failures. Users that ask for this feature are generally unconcerned with verifiability.
- Applying the attribute at higher levels than an individual method has nonlocal effect, which is observable when `stackalloc` is used. Yet, this is the most requested scenario.

Alternatives

- omit `localinits` flag when method is declared in `unsafe` context. That could cause silent and dangerous behavior change from deterministic to nondeterministic in a case of `stackalloc`.
- omit `localinits` flag always. Even worse than above.
- omit `localinits` flag unless `stackalloc` is used in the method body. Does not address the most requested scenario and may turn code unverifiable with no option to revert that back.

Unresolved questions

- Should the attribute be actually emitted to metadata?

Design meetings

None yet.

Unconstrained type parameter annotations

Article • 2021-09-21 • 2 minutes to read

Summary

Allow nullable annotations for type parameters that are not constrained to value types or reference types: `T?`.

C#

```
static T? FirstOrDefault<T>(this IEnumerable<T> collection) { ... }
```

? annotation

In C#8, `?` annotations could only be applied to type parameters that were explicitly constrained to value types or reference types. In C#9, `?` annotations can be applied to any type parameter, regardless of constraints.

Unless a type parameter is explicitly constrained to value types, annotations can only be applied within a `#nullable enable` context.

If a type parameter `T` is substituted with a reference type, then `T?` represents a nullable instance of that reference type.

C#

```
var s1 = new string[0].FirstOrDefault(); // string? s1  
var s2 = new string?[0].FirstOrDefault(); // string? s2
```

If `T` is substituted with a value type, then `T?` represents an instance of `T`.

C#

```
var i1 = new int[0].FirstOrDefault(); // int i1  
var i2 = new int?[0].FirstOrDefault(); // int? i2
```

If `T` is substituted with an annotated type `U?`, then `T?` represents the annotated type `U?` rather than `U??`.

C#

```
var u1 = new U[0].FirstOrDefault(); // U? u1
var u2 = new U?[0].FirstOrDefault(); // U? u2
```

If `T` is substituted with a type `U`, then `T?` represents `U?`, even within a `nullable disable` context.

C#

```
nullable disable
var u3 = new U[0].FirstOrDefault(); // U? u3
```

For return values, `T?` is equivalent to `[MaybeNull]T`; for argument values, `T?` is equivalent to `[AllowNull]T`. The equivalence is important when overriding or implementing interfaces from an assembly compiled with C#8.

C#

```
public abstract class A
{
    [return: MaybeNull] public abstract T F1<T>();
    public abstract void F2<T>([AllowNull] T t);
}

public class B : A
{
    public override T? F1<T>() where T : default { ... } // matches
    A.F1<T>()
    public override void F2<T>(T? t) where T : default { ... } // matches
    A.F2<T>()
}

```

default constraint

For compatibility with existing code where overridden and explicitly implemented generic methods could not include explicit constraint clauses, `T?` in an overridden or explicitly implemented method is treated as `Nullable<T>` where `T` is a value type.

To allow annotations for type parameters constrained to reference types, C#8 allowed explicit `where T : class` and `where T : struct` constraints on the overridden or explicitly implemented method.

C#

```

class A1
{
    public virtual void F1<T>(T? t) where T : struct { }
    public virtual void F1<T>(T? t) where T : class { }
}

class B1 : A1
{
    public override void F1<T>(T? t) /*where T : struct*/ { }
    public override void F1<T>(T? t) where T : class { }
}

```

To allow annotations for type parameters that are not constrained to reference types or value types, C#9 allows a new `where T : default` constraint.

```

C#

class A2
{
    public virtual void F2<T>(T? t) where T : struct { }
    public virtual void F2<T>(T? t) { }
}

class B2 : A2
{
    public override void F2<T>(T? t) /*where T : struct*/ { }
    public override void F2<T>(T? t) where T : default { }
}

```

It is an error to use a `default` constraint other than on a method override or explicit implementation. It is an error to use a `default` constraint when the corresponding type parameter in the overridden or interface method is constrained to a reference type or value type.

Record structs

Article • 2022-02-23 • 10 minutes to read

The syntax for a record struct is as follows:

```
antlr

record_struct_declaration
    : attributes? struct_modifier* 'partial'? 'record' 'struct' identifier
    type_parameter_list?
      parameter_list? struct_interfaces? type_parameter_constraints_clause*
    record_struct_body
    ;

record_struct_body
    : struct_body
    | ';'
    ;
```

Record struct types are value types, like other struct types. They implicitly inherit from the class `System.ValueType`. The modifiers and members of a record struct are subject to the same restrictions as those of structs (accessibility on type, modifiers on members, `base(...)` instance constructor initializers, definite assignment for `this` in constructor, destructors, ...). Record structs will also follow the same rules as structs for parameterless instance constructors and field initializers, but this document assumes that we will lift those restrictions for structs generally.

See [§15.4.9](#) See [parameterless struct constructors](#) spec.

Record structs cannot use `ref` modifier.

At most one partial type declaration of a partial record struct may provide a `parameter_list`. The `parameter_list` may be empty.

Record struct parameters cannot use `ref`, `out` or `this` modifiers (but `in` and `params` are allowed).

Members of a record struct

In addition to the members declared in the record struct body, a record struct type has additional synthesized members. Members are synthesized unless a member with a "matching" signature is declared in the record struct body or an accessible concrete non-virtual member with a "matching" signature is inherited. Two members are

considered matching if they have the same signature or would be considered "hiding" in an inheritance scenario. See Signatures and overloading §7.6. It is an error for a member of a record struct to be named "Clone".

It is an error for an instance field of a record struct to have an unsafe type.

A record struct is not permitted to declare a destructor.

The synthesized members are as follows:

Equality members

The synthesized equality members are similar as in a record class (`Equals` for this type, `Equals` for `object` type, `==` and `!=` operators for this type), except for the lack of `EqualityContract`, null checks or inheritance.

The record struct implements `System.IEquatable<R>` and includes a synthesized strongly-typed overload of `Equals(R other)` where `R` is the record struct. The method is `public`. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility.

If `Equals(R other)` is user-defined (not synthesized) but `GetHashCode` is not, a warning is produced.

```
C#
```

```
public readonly bool Equals(R other);
```

The synthesized `Equals(R)` returns `true` if and only if for each instance field `fieldN` in the record struct the value of

```
System.Collections.Generic.EqualityComparer<TN>.Default.Equals(fieldN,  
other.fieldN) where TN is the field type is true.
```

The record struct includes synthesized `==` and `!=` operators equivalent to operators declared as follows:

```
C#
```

```
public static bool operator==(R r1, R r2)  
    => r1.Equals(r2);  
public static bool operator!=(R r1, R r2)  
    => !(r1 == r2);
```

The `Equals` method called by the `==` operator is the `Equals(R other)` method specified above. The `!=` operator delegates to the `==` operator. It is an error if the operators are declared explicitly.

The record struct includes a synthesized override equivalent to a method declared as follows:

```
C#  
  
public override readonly bool Equals(object? obj);
```

It is an error if the override is declared explicitly. The synthesized override returns `other is R temp && Equals(temp)` where `R` is the record struct.

The record struct includes a synthesized override equivalent to a method declared as follows:

```
C#  
  
public override readonly int GetHashCode();
```

The method can be declared explicitly.

A warning is reported if one of `Equals(R)` and `GetHashCode()` is explicitly declared but the other method is not explicit.

The synthesized override of `GetHashCode()` returns an `int` result of combining the values of `System.Collections.Generic.EqualityComparer<TN>.Default.GetHashCode(fieldN)` for each instance field `fieldN` with `TN` being the type of `fieldN`.

For example, consider the following record struct:

```
C#  
  
record struct R1(T1 P1, T2 P2);
```

For this record struct, the synthesized equality members would be something like:

```
C#  
  
struct R1 : IEquatable<R1>  
{  
    public T1 P1 { get; set; }  
    public T2 P2 { get; set; }  
}
```

```

    public override bool Equals(object? obj) => obj is R1 temp &&
Equals(temp);
    public bool Equals(R1 other)
    {
        return
            EqualityComparer<T1>.Default.Equals(P1, other.P1) &&
            EqualityComparer<T2>.Default.Equals(P2, other.P2);
    }
    public static bool operator==(R1 r1, R1 r2)
        => r1.Equals(r2);
    public static bool operator!=(R1 r1, R1 r2)
        => !(r1 == r2);
    public override int GetHashCode()
    {
        return Combine(
            EqualityComparer<T1>.Default.GetHashCode(P1),
            EqualityComparer<T2>.Default.GetHashCode(P2));
    }
}

```

Printing members: PrintMembers and ToString methods

The record struct includes a synthesized method equivalent to a method declared as follows:

```

C#

private bool PrintMembers(System.Text.StringBuilder builder);

```

The method does the following:

1. for each of the record struct's printable members (non-static public field and readable property members), appends that member's name followed by " = " followed by the member's value separated with ", ",
2. return true if the record struct has printable members.

For a member that has a value type, we will convert its value to a string representation using the most efficient method available to the target platform. At present that means calling `ToString` before passing to `StringBuilder.Append`.

If the record's printable members do not include a readable property with a non-`readonly` `get` accessor, then the synthesized `PrintMembers` is `readonly`. There is no requirement for the record's fields to be `readonly` for the `PrintMembers` method to be `readonly`.

The `PrintMembers` method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility.

The record struct includes a synthesized method equivalent to a method declared as follows:

```
C#  
  
public override string ToString();
```

If the record struct's `PrintMembers` method is `readonly`, then the synthesized `ToString()` method is `readonly`.

The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility.

The synthesized method:

1. creates a `StringBuilder` instance,
2. appends the record struct name to the builder, followed by " { ",
3. invokes the record struct's `PrintMembers` method giving it the builder, followed by " " if it returned true,
4. appends "}",
5. returns the builder's contents with `builder.ToString()`.

For example, consider the following record struct:

```
C#  
  
record struct R1(T1 P1, T2 P2);
```

For this record struct, the synthesized printing members would be something like:

```
C#  
  
struct R1 : IEquatable<R1>  
{  
    public T1 P1 { get; set; }  
    public T2 P2 { get; set; }  
  
    private bool PrintMembers(StringBuilder builder)  
    {  
        builder.Append(nameof(P1));  
        builder.Append(" = ");  
        builder.Append(this.P1); // or builder.Append(this.P1.ToString());  
        if P1 has a value type
```

```

        builder.Append(", ");

        builder.Append(nameof(P2));
        builder.Append(" = ");
        builder.Append(this.P2); // or builder.Append(this.P2.ToString());
    if P2 has a value type

        return true;
    }

    public override string ToString()
    {
        var builder = new StringBuilder();
        builder.Append(nameof(R1));
        builder.Append(" { ");

        if (PrintMembers(builder))
            builder.Append(" ");

        builder.Append("}");
        return builder.ToString();
    }
}

```

Positional record struct members

In addition to the above members, record structs with a parameter list ("positional records") synthesize additional members with the same conditions as the members above.

Primary Constructor

A record struct has a public constructor whose signature corresponds to the value parameters of the type declaration. This is called the primary constructor for the type. It is an error to have a primary constructor and a constructor with the same signature already present in the struct. If the type declaration does not include a parameter list, no primary constructor is generated.

C#

```

record struct R1
{
    public R1() { } // ok
}

record struct R2()
{
    public R2() { } // error: 'R2' already defines constructor with same

```

```
parameter types
}
```

Instance field declarations for a record struct are permitted to include variable initializers. If there is no primary constructor, the instance initializers execute as part of the parameterless constructor. Otherwise, at runtime the primary constructor executes the instance initializers appearing in the record-struct-body.

If a record struct has a primary constructor, any user-defined constructor must have an explicit `this` constructor initializer that calls the primary constructor or an explicitly declared constructor.

Parameters of the primary constructor as well as members of the record struct are in scope within initializers of instance fields or properties. Instance members would be an error in these locations (similar to how instance members are in scope in regular constructor initializers today, but an error to use), but the parameters of the primary constructor would be in scope and useable and would shadow members. Static members would also be useable.

A warning is produced if a parameter of the primary constructor is not read.

The definite assignment rules for struct instance constructors apply to the primary constructor of record structs. For instance, the following is an error:

```
C#
record struct Pos(int X) // definite assignment error in primary constructor
{
    private int x;
    public int X { get { return x; } set { x = value; } } = X;
}
```

Properties

For each record struct parameter of a record struct declaration there is a corresponding public property member whose name and type are taken from the value parameter declaration.

For a record struct:

- A public `get` and `init` auto-property is created if the record struct has `readonly` modifier, `get` and `set` otherwise. Both kinds of set accessors (`set` and `init`) are considered "matching". So the user may declare an init-only property in place of a synthesized mutable one. An inherited `abstract` property with matching type is

overridden. No auto-property is created if the record struct has an instance field with expected name and type. It is an error if the inherited property does not have `public` `get` and `set/init` accessors. It is an error if the inherited property or field is hidden.

The auto-property is initialized to the value of the corresponding primary constructor parameter. Attributes can be applied to the synthesized auto-property and its backing field by using `property:` or `field:` targets for attributes syntactically applied to the corresponding record struct parameter.

Deconstruct

A positional record struct with at least one parameter synthesizes a public void-returning instance method called `Deconstruct` with an out parameter declaration for each parameter of the primary constructor declaration. Each parameter of the `Deconstruct` method has the same type as the corresponding parameter of the primary constructor declaration. The body of the method assigns each parameter of the `Deconstruct` method to the value from an instance member access to a member of the same name. If the instance members accessed in the body do not include a property with a non-`readonly` `get` accessor, then the synthesized `Deconstruct` method is `readonly`. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or is static.

Allow `with` expression on structs

It is now valid for the receiver in a `with` expression to have a struct type.

On the right hand side of the `with` expression is a `member_initializer_list` with a sequence of assignments to *identifier*, which must be an accessible instance field or property of the receiver's type.

For a receiver with struct type, the receiver is first copied, then each `member_initializer` is processed the same way as an assignment to a field or property access of the result of the conversion. Assignments are processed in lexical order.

Improvements on records

Allow `record class`

The existing syntax for record types allows `record class` with the same meaning as `record`:

```
antlr
```

```
record_declaration
    : attributes? class_modifier* 'partial'? 'record' 'class'? identifier
  type_parameter_list?
    parameter_list? record_base? type_parameter_constraints_clause*
  record_body
    ;
```

Allow user-defined positional members to be fields

See <https://github.com/dotnet/csharpplang/blob/master/meetings/2020/LDM-2020-10-05.md#changing-the-member-type-of-a-primary-constructor-parameter>

No auto-property is created if the record has or inherits an instance field with expected name and type.

Allow parameterless constructors and member initializers in structs

See [parameterless struct constructors](#) spec.

Open questions

- how to recognize record structs in metadata? (we don't have an unspeakable clone method to leverage...)

Answered

- confirm that we want to keep PrintMembers design (separate method returning `bool`) (answer: yes)
- confirm we won't allow `record ref struct` (issue with `IEquatable<RefStruct>` and ref fields) (answer: yes)
- confirm implementation of equality members. Alternative is that synthesized `bool Equals(R other)`, `bool Equals(object? other)` and operators all just delegate to `ValueType.Equals`. (answer: yes)

- confirm that we want to allow field initializers when there is a primary constructor. Do we also want to allow parameterless struct constructors while we're at it (the Activator issue was apparently fixed)? (answer: yes, updated spec should be reviewed in LDM)
- how much do we want to say about `Combine` method? (answer: as little as possible)
- should we disallow a user-defined constructor with a copy constructor signature? (answer: no, there is no notion of copy constructor in the record structs spec)
- confirm that we want to disallow members named "Clone". (answer: correct)
- double-check that synthesized `Equals` logic is functionally equivalent to runtime implementation (e.g. `float.NaN`) (answer: confirmed in LDM)
- could field- or property-targeting attributes be placed in the positional parameter list? (answer: yes, same as for record class)
- `with` on generics? (answer: out of scope for C# 10)
- should `GetHashCode` include a hash of the type itself, to get different values between `record struct S1;` and `record struct S2;`? (answer: no)

Parameterless struct constructors

Article • 2022-04-02 • 7 minutes to read

Summary

Support parameterless constructors and instance field initializers for struct types.

Motivation

Explicit parameterless constructors would give more control over minimally constructed instances of the struct type. Instance field initializers would allow simplified initialization across multiple constructors. Together these would close an obvious gap between `struct` and `class` declarations.

Support for field initializers would also allow initialization of fields in `record struct` declarations without explicitly implementing the primary constructor.

```
C#
```

```
record struct Person(string Name)
{
    public object Id { get; init; } = GetNextId();
}
```

If struct field initializers are supported for constructors with parameters, it seems natural to extend that to parameterless constructors as well.

```
C#
```

```
record struct Person()
{
    public string Name { get; init; }
    public object Id { get; init; } = GetNextId();
}
```

Proposal

Instance field initializers

Instance field declarations for a struct may include initializers.

As with class field initializers [§14.5.6.3](#) ↗:

A variable initializer for an instance field cannot reference the instance being created.

An error is reported if a struct has field initializers and no declared instance constructors since the field initializers will not be run.

C#

```
struct S { int F = 42; } // error: 'struct' with field initializers must include an explicitly declared constructor
```

Constructors

A struct may declare a parameterless instance constructor.

A parameterless instance constructor is valid for all struct kinds including `struct`, `readonly struct`, `ref struct`, and `record struct`.

If no parameterless instance constructor is declared, the struct (see [§15.4.9](#) ↗) ...

implicitly has a parameterless instance constructor which always returns the value that results from setting all value type fields to their default value and all reference type fields to null.

Modifiers

A parameterless instance struct constructor must be declared `public`.

C#

```
struct S0 { } // ok
struct S1 { public S1() { } } // ok
struct S2 { internal S2() { } } // error: parameterless constructor must be 'public'
```

Non-public constructors are ignored when importing types from metadata.

Constructors can be declared `extern` or `unsafe`. Constructors cannot be `partial`.

Executing field initializers

Instance variable initializers ([§14.11.3](#)) is **modified** as follows:

When a **class** instance constructor has no constructor initializer, or it has a constructor initializer of the form `base(...)`, that constructor implicitly performs the initializations specified by the *variable_initializers* of the instance fields declared in its class. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor and before the implicit invocation of the direct base class constructor.

When a **struct** instance constructor has no constructor initializer, that constructor implicitly performs the initializations specified by the *variable_initializers* of the instance fields declared in its struct. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor.

When a **struct** instance constructor has a `this()` constructor initializer that represents the *default parameterless constructor*, the declared constructor implicitly clears all instance fields and performs the initializations specified by the *variable_initializers* of the instance fields declared in its struct. Immediately upon entry to the constructor, all value type fields are set to their default value and all reference type fields are set to `null`. Immediately after that, a sequence of assignments corresponding to the *variable_initializers* are executed.

Definite assignment

Instance fields (other than `fixed` fields) must be definitely assigned in struct instance constructors that do not have a `this()` initializer (see [§15.4.9](#)).

C#

```
struct S0 // ok
{
    int x;
    object y;
}

struct S1 // error: 'struct' with field initializers must include an
explicitly declared constructor
{
    int x = 1;
    object y;
}

struct S2
{
    int x = 1;
    object y;
}
```

```

    public S2() { } // error: field 'y' must be assigned
}

struct S3 // ok
{
    int x = 1;
    object y;
    public S3() { y = 2; }
}

```

No `base()` initializer

A `base()` initializer is disallowed in struct constructors.

The compiler will not emit a call to the base `System.ValueType` constructor from struct instance constructors.

record struct

An error is reported if a `record struct` has field initializers and does not contain a primary constructor nor any instance constructors since the field initializers will not be run.

C#

```

record struct R0; // ok
record struct R1 { int F = 42; } // error: 'struct' with field
initializers must include an explicitly declared constructor
record struct R2() { int F = 42; } // ok
record struct R3(int F); // ok

```

A `record struct` with an empty parameter list will have a parameterless primary constructor.

C#

```

record struct R3(); // primary .ctor: public R3() { }
record struct R4() { int F = 42; } // primary .ctor: public R4() { F = 42; }

```

An explicit parameterless constructor in a `record struct` must have a `this` initializer that calls the primary constructor or an explicitly declared constructor.

C#

```

record struct R5(int F)
{
    public R5() { } // error: must have 'this' initializer
    that calls explicit .ctor
    public R5(object o) : this() { } // ok
    public int F = F;
}

```

Fields

The implicitly-defined parameterless constructor will zero fields rather than calling any parameterless constructors for the field types. No warnings are reported that field constructors are ignored. *No change from C#9.*

```

C#

struct S0
{
    public S0() { }
}

struct S1
{
    S0 F; // S0 constructor ignored
}

struct S<T> where T : struct
{
    T F; // constructor (if any) ignored
}

```

default expression

`default` ignores the parameterless constructor and generates a zeroed instance. *No change from C#9.*

```

C#

// struct S { public S() { } }

_ = default(S); // constructor ignored, no warning

```

new()

Object creation invokes the parameterless constructor if public; otherwise the instance is zeroed. *No change from C#9.*

C#

```
// public struct PublicConstructor { public PublicConstructor() { } }
// public struct PrivateConstructor { private PrivateConstructor() { } }

_ = new PublicConstructor(); // call PublicConstructor::.ctor()
_ = new PrivateConstructor(); // initobj PrivateConstructor
```

A warning wave may report a warning for use of `new()` with a struct type that has constructors but no parameterless constructor. No warning will be reported when using substituting such a struct type for a type parameter with a `new()` or `struct` constraint.

C#

```
struct S { public S(int i) { } }
static T CreateNew<T>() where T : new() => new T();

_ = new S(); // warning: no constructor called
_ = CreateNew<S>(); // ok
```

Uninitialized values

A local or field of a struct type that is not explicitly initialized is zeroed. The compiler reports a definite assignment error for an uninitialized struct that is not empty. *No change from C#9.*

C#

```
NoConstructor s1;
PublicConstructor s2;
s1.ToString(); // error: use of unassigned local (unless type is empty)
s2.ToString(); // error: use of unassigned local (unless type is empty)
```

Array allocation

Array allocation ignores any parameterless constructor and generates zeroed elements. *No change from C#9.*

C#

```
// struct S { public S() { } }
```

```
var a = new S[1]; // constructor ignored, no warning
```

Parameter default value `new()`

A parameter default value of `new()` binds to the parameterless constructor if public (and reports an error that the value is not constant); otherwise the instance is zeroed. *No change from C#9.*

C#

```
// public struct PublicConstructor { public PublicConstructor() { } }
// public struct PrivateConstructor { private PrivateConstructor() { } }

static void F1(PublicConstructor s1 = new()) { } // error: default value
must be constant
static void F2(PrivateConstructor s2 = new()) { } // ok: initobj
```

Type parameter constraints: `new()` and `struct`

The `new()` and `struct` type parameter constraints require the parameterless constructor to be `public` if defined (see Satisfying constraints - [§8.4.5](#)).

The compiler assumes all structs satisfy `new()` and `struct` constraints. *No change from C#9.*

C#

```
// public struct PublicConstructor { public PublicConstructor() { } }
// public struct InternalConstructor { internal InternalConstructor() { } }

static T CreateNew<T>() where T : new() => new T();
static T CreateStruct<T>() where T : struct => new T();

_ = CreateNew<PublicConstructor>(); // ok
_ = CreateStruct<PublicConstructor>(); // ok

_ = CreateNew<InternalConstructor>(); // compiles; may fail at runtime
_ = CreateStruct<InternalConstructor>(); // compiles; may fail at runtime
```

`new T()` is emitted as a call to `System.Activator.CreateInstance<T>()`, and the compiler assumes the implementation of `CreateInstance<T>()` invokes the `public` parameterless constructor if defined.

With .NET Framework, `Activator.CreateInstance<T>()` invokes the parameterless constructor if the constraint is `where T : new()` but appears to ignore the parameterless constructor if the constraint is `where T : struct`.

Optional parameters

Constructors with optional parameters are not considered parameterless constructors. *No change from C#9.*

C#

```
struct S1 { public S1(string s = "") { } }
struct S2 { public S2(params object[] args) { } }

_ = new S1(); // ok: ignores constructor
_ = new S2(); // ok: ignores constructor
```

Metadata

Explicit parameterless struct instance constructors will be emitted to metadata.

Public parameterless struct instance constructors will be imported from metadata; non-public struct instance constructors will be ignored. *No change from C#9.*

Global Using Directive

Article • 2022-03-24 • 13 minutes to read

Syntax for a using directive is extended with an optional `global` keyword that can precede the `using` keyword:

```
antlr
```

```
compilation_unit
    : extern_alias_directive* global_using_directive* using_directive*
  global_attributes? namespace_member_declaration*
    ;

global_using_directive
    : global_using_alias_directive
  | global_using_namespace_directive
  | global_using_static_directive
    ;

global_using_alias_directive
    : 'global' 'using' identifier '=' namespace_or_type_name ';'
    ;

global_using_namespace_directive
    : 'global' 'using' namespace_name ';'
    ;

global_using_static_directive
    : 'global' 'using' 'static' type_name ';'
    ;
```

- The *global_using_directives* are allowed only on the Compilation Unit level (cannot be used inside a *namespace_declaration*).
- The *global_using_directives*, if any, must precede any *using_directives*.
- The scope of a *global_using_directives* extends over the *namespace_member_declarations* of all compilation units within the program. The scope of a *global_using_directive* specifically does not include other *global_using_directives*. Thus, peer *global_using_directives* or those from a different compilation unit do not affect each other, and the order in which they are written is insignificant. The scope of a *global_using_directive* specifically does not include *using_directives* immediately contained in any compilation unit of the program.

The effect of adding a *global_using_directive* to a program can be thought of as the effect of adding a similar *using_directive* that resolves to the same target namespace or type to every compilation unit of the program. However, the target of a *global_using_directive* is resolved in context of the compilation unit that contains it.

§7.7 [↗](#) Scopes

These are the relevant bullet points with proposed additions (which are **in bold**):

- The scope of name defined by an *extern_alias_directive* extends over the ***global_using_directives***, *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing compilation unit or namespace body. An *extern_alias_directive* does not contribute any new members to the underlying declaration space. In other words, an *extern_alias_directive* is not transitive, but, rather, affects only the compilation unit or namespace body in which it occurs.
- The scope of a name defined or imported by a ***global_using_directive*** extends over the ***global_attributes*** and ***namespace_member_declarations*** of all the ***compilation_units*** in the program.

§7.8 [↗](#) Namespace and type names

Changes are made to the algorithm determining the meaning of a *namespace_or_type_name* as follows.

This is the relevant bullet point with proposed additions (which are **in bold**):

- If the *namespace_or_type_name* is of the form **I** or of the form **I<A1, ..., Ak>**:
 - If **K** is zero and the *namespace_or_type_name* appears within a generic method declaration (§14.6 [↗](#)) and if that declaration includes a type parameter (§14.2.3 [↗](#)) with name **I**, then the *namespace_or_type_name* refers to that type parameter.
 - Otherwise, if the *namespace_or_type_name* appears within a type declaration, then for each instance type **T** (§14.3.2 [↗](#)), starting with the instance type of that type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):
 - If **K** is zero and the declaration of **T** includes a type parameter with name **I**, then the *namespace_or_type_name* refers to that type parameter.
 - Otherwise, if the *namespace_or_type_name* appears within the body of the type declaration, and **T** or any of its base types contain a nested accessible type having name **I** and **K** type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments. If there is more than one such type, the type declared within the more derived type is selected. Note that non-type members (constants, fields, methods, properties, indexers, operators, instance constructors, destructors, and static constructors) and type members with a different

- number of type parameters are ignored when determining the meaning of the *namespace_or_type_name*.
- If the previous steps were unsuccessful then, for each namespace **N**, starting with the namespace in which the *namespace_or_type_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
 - If **K** is zero and **I** is the name of a namespace in **N**, then:
 - If the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for **N** and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with a namespace or type, **or any namespace declaration for **N** in the program contains a *global_using_alias_directive* that associates the name **I** with a namespace or type**, then the *namespace_or_type_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the namespace named **I** in **N**.
 - Otherwise, if **N** contains an accessible type having name **I** and **K** type parameters, then:
 - If **K** is zero and the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for **N** and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with a namespace or type, **or any namespace declaration for **N** in the program contains a *global_using_alias_directive* that associates the name **I** with a namespace or type**, then the *namespace_or_type_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the type constructed with the given type arguments.
 - Otherwise, if the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for **N**:
 - If **K** is zero and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with an imported namespace or type, **or any namespace declaration for **N** in the program contains a *global_using_alias_directive* that associates the name **I** with an imported namespace or type**, then the *namespace_or_type_name* refers to that namespace or type.
 - Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_alias_directives* of the namespace declaration **and the namespaces and type declarations imported by the *global_using_namespace_directives* and *global_using_static_directives* of**

- any namespace declaration for **N** in the program contain exactly one accessible type having name **I** and **K** type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments.
- Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_alias_directives* of the namespace declaration and the namespaces and type declarations imported by the *global_using_namespace_directives* and *global_using_static_directives* of any namespace declaration for **N** in the program contain more than one accessible type having name **I** and **K** type parameters, then the *namespace_or_type_name* is ambiguous and an error occurs.
- Otherwise, the *namespace_or_type_name* is undefined and a compile-time error occurs.

Simple names §11.7.4 [↗](#)

Changes are made to the *simple_name* evaluation rules as follows.

This is the relevant bullet point with proposed additions (which are **in bold**):

- Otherwise, for each namespace **N**, starting with the namespace in which the *simple_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
 - If **K** is zero and **I** is the name of a namespace in **N**, then:
 - If the location where the *simple_name* occurs is enclosed by a namespace declaration for **N** and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with a namespace or type, **or any namespace declaration for **N** in the program contains a *global_using_alias_directive* that associates the name **I** with a namespace or type**, then the *simple_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *simple_name* refers to the namespace named **I** in **N**.
 - Otherwise, if **N** contains an accessible type having name **I** and **K** type parameters, then:
 - If **K** is zero and the location where the *simple_name* occurs is enclosed by a namespace declaration for **N** and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with a namespace or type, **or any namespace declaration for **N** in the program contains a *global_using_alias_directive* that associates the name **I** with a**

- namespace or type, then the *simple_name* is ambiguous and a compile-time error occurs.
- Otherwise, the *namespace_or_type_name* refers to the type constructed with the given type arguments.
 - Otherwise, if the location where the *simple_name* occurs is enclosed by a namespace declaration for **N**:
 - If **K** is zero and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with an imported namespace or type, **or any namespace declaration for **N** in the program contains a *global_using_alias_directive* that associates the name **I** with an imported namespace or type**, then the *simple_name* refers to that namespace or type.
 - Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_static_directives* of the namespace declaration **and the namespaces and type declarations imported by the *global_using_namespace_directives* and *global_using_static_directives* of any namespace declaration for **N** in the program** contain exactly one accessible type or non-extension static member having name **I** and **K** type parameters, then the *simple_name* refers to that type or member constructed with the given type arguments.
 - Otherwise, if the namespaces and types imported by the *using_namespace_directives* of the namespace declaration **and the namespaces and type declarations imported by the *global_using_namespace_directives* and *global_using_static_directives* of any namespace declaration for **N** in the program** contain more than one accessible type or non-extension-method static member having name **I** and **K** type parameters, then the *simple_name* is ambiguous and an error occurs.

Extension method invocations §11.7.8.3 [↗](#)

Changes are made to the algorithm to find the best *type_name* **C** as follows. This is the relevant bullet point with proposed additions (which are **in bold**):

- Starting with the closest enclosing namespace declaration, continuing with each enclosing namespace declaration, and ending with the containing compilation unit, successive attempts are made to find a candidate set of extension methods:
 - If the given namespace or compilation unit directly contains non-generic type declarations **C_i** with eligible extension methods **M_j**, then the set of those extension methods is the candidate set.

- If types `Ci` imported by *using_static_declarations* and directly declared in namespaces imported by *using_namespace_directives* in the given namespace or compilation unit and, if containing compilation unit is reached, imported by *global_using_static_declarations* and directly declared in namespaces imported by *global_using_namespace_directives* in the program directly contain eligible extension methods `Mj`, then the set of those extension methods is the candidate set.

Compilation units §13.2 [↗](#)

A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of **zero or more *global_using_directives* followed by zero or more *using_directives*** followed by zero or more *global_attributes* followed by zero or more *namespace_member_declarations*.

```
antlr
```

```
compilation_unit
    : extern_alias_directive* global_using_directive* using_directive*
  global_attributes? namespace_member_declaration*
  ;
```

A C# program consists of one or more compilation units, each contained in a separate source file. When a C# program is compiled, all of the compilation units are processed together. Thus, compilation units can depend on each other, possibly in a circular fashion.

The *global_using_directives* of a compilation unit affect the *global_attributes* and *namespace_member_declarations* of all compilation units in the program.

Extern aliases §13.4 [↗](#)

The scope of an *extern_alias_directive* extends over the *global_using_directives*, *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing compilation unit or namespace body.

Using alias directives §13.5.2 [↗](#)

The order in which *using_alias_directives* are written has no significance, and resolution of the *namespace_or_type_name* referenced by a *using_alias_directive* is not affected by the *using_alias_directive* itself or by other *using_directives* in the immediately containing

compilation unit or namespace body, and, if the *using_alias_directive* is immediately contained in a compilation unit, is not affected by the *global_using_directives* in the program. In other words, the *namespace_or_type_name* of a *using_alias_directive* is resolved as if the immediately containing compilation unit or namespace body had no *using_directives* and, if the *using_alias_directive* is immediately contained in a compilation unit, the program had no *global_using_directives*. A *using_alias_directive* may however be affected by *extern_alias_directives* in the immediately containing compilation unit or namespace body.

Global Using alias directives

A *global_using_alias_directive* introduces an identifier that serves as an alias for a namespace or type within the program.

```
antlr
```

```
global_using_alias_directive
    : 'global' 'using' identifier '=' namespace_or_type_name ';'
    ;
```

Within member declarations in any compilation unit of a program that contains a *global_using_alias_directive*, the identifier introduced by the *global_using_alias_directive* can be used to reference the given namespace or type.

The *identifier* of a *global_using_alias_directive* must be unique within the declaration space of any compilation unit of a program that contains the *global_using_alias_directive*.

Just like regular members, names introduced by *global_using_alias_directives* are hidden by similarly named members in nested scopes.

The order in which *global_using_alias_directives* are written has no significance, and resolution of the *namespace_or_type_name* referenced by a *global_using_alias_directive* is not affected by the *global_using_alias_directive* itself or by other *global_using_directives* or *using_directives* in the program. In other words, the *namespace_or_type_name* of a *global_using_alias_directive* is resolved as if the immediately containing compilation unit had no *using_directives* and the entire containing program had no *global_using_directives*. A *global_using_alias_directive* may however be affected by *extern_alias_directives* in the immediately containing compilation unit.

A *global_using_alias_directive* can create an alias for any namespace or type.

Accessing a namespace or type through an alias yields exactly the same result as accessing that namespace or type through its declared name.

Using aliases can name a closed constructed type, but cannot name an unbound generic type declaration without supplying type arguments.

Global Using namespace directives

A *global_using_namespace_directive* imports the types contained in a namespace into the program, enabling the identifier of each type to be used without qualification.

```
antlr
```

```
global_using_namespace_directive  
  : 'global' 'using' namespace_name ';' ;  
  ;
```

Within member declarations in a program that contains a *global_using_namespace_directive*, the types contained in the given namespace can be referenced directly.

A *global_using_namespace_directive* imports the types contained in the given namespace, but specifically does not import nested namespaces.

Unlike a *global_using_alias_directive*, a *global_using_namespace_directive* may import types whose identifiers are already defined within a compilation unit of the program. In effect, in a given compilation unit, names imported by any *global_using_namespace_directive* in the program are hidden by similarly named members in the compilation unit.

When more than one namespace or type imported by *global_using_namespace_directives* or *global_using_static_directives* in the same program contain types by the same name, references to that name as a *type_name* are considered ambiguous.

Furthermore, when more than one namespace or type imported by *global_using_namespace_directives* or *global_using_static_directives* in the same program contain types or members by the same name, references to that name as a *simple_name* are considered ambiguous.

The *namespace_name* referenced by a *global_using_namespace_directive* is resolved in the same way as the *namespace_or_type_name* referenced by a

global_using_alias_directive. Thus, *global_using_namespace_directives* in the same program do not affect each other and can be written in any order.

Global Using static directives

A *global_using_static_directive* imports the nested types and static members contained directly in a type declaration into the containing program, enabling the identifier of each member and type to be used without qualification.

```
antlr
```

```
global_using_static_directive
: 'global' 'using' 'static' type_name ';'
;
```

Within member declarations in a program that contains a *global_using_static_directive*, the accessible nested types and static members (except extension methods) contained directly in the declaration of the given type can be referenced directly.

A *global_using_static_directive* specifically does not import extension methods directly as static methods, but makes them available for extension method invocation.

A *global_using_static_directive* only imports members and types declared directly in the given type, not members and types declared in base classes.

Ambiguities between multiple *global_using_namespace_directives* and *global_using_static_directives* are discussed in the section for *global_using_namespace_directives* (above).

Qualified alias member §13.8 [↗](#)

Changes are made to the algorithm determining the meaning of a *qualified_alias_member* as follows.

This is the relevant bullet point with proposed additions (which are **in bold**):

- Otherwise, starting with the namespace declaration ([§13.3](#) [↗](#)) immediately containing the *qualified_alias_member* (if any), continuing with each enclosing namespace declaration (if any), and ending with the compilation unit containing the *qualified_alias_member*, the following steps are evaluated until an entity is located:
 - If the namespace declaration or compilation unit contains a *using_alias_directive* that associates **N** with a type, **or, when a compilation unit is reached, the**

- program contains a *global_using_alias_directive* that associates **N** with a type, then the *qualified_alias_member* is undefined and a compile-time error occurs.
- Otherwise, if the namespace declaration or compilation unit contains an *extern_alias_directive* or *using_alias_directive* that associates **N** with a namespace, **or, when a compilation unit is reached, the program contains a *global_using_alias_directive* that associates **N** with a namespace**, then:
 - If the namespace associated with **N** contains a namespace named **I** and **K** is zero, then the *qualified_alias_member* refers to that namespace.
 - Otherwise, if the namespace associated with **N** contains a non-generic type named **I** and **K** is zero, then the *qualified_alias_member* refers to that type.
 - Otherwise, if the namespace associated with **N** contains a type named **I** that has **K** type parameters, then the *qualified_alias_member* refers to that type constructed with the given type arguments.
 - Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.

File Scoped Namespaces

Article • 2022-02-23 • 2 minutes to read

Summary

File scoped namespaces use a less verbose format for the typical case of files containing only one namespace. The file scoped namespace format is `namespace X.Y.Z;` (note the semicolon and lack of braces). This allows for files like the following:

```
c#  
  
namespace X.Y.Z;  
  
using System;  
  
class X  
{  
}
```

The semantics are that using the `namespace X.Y.Z;` form is equivalent to writing `namespace X.Y.Z { ... }` where the remainder of the file following the file-scoped namespace is in the `...` section of a standard namespace declaration.

Motivation

Analysis of the C# ecosystem shows that approximately 99.7% files are all of either one of these forms:

```
c#  
  
namespace X.Y.Z  
{  
    // usings  
  
    // types  
}
```

or

```
c#  
  
// usings
```

```
namespace X.Y.Z
{
    // types
}
```

However, both these forms force the user to indent the majority of their code and add a fair amount of ceremony for what is effectively a very basic concept. This affects clarity, uses horizontal and vertical space, and is often unsatisfying for users both used to C# and coming from other languages (which commonly have less ceremony here).

The primary goal of the feature therefore is to meet the needs of the majority of the ecosystem with less unnecessary boilerplate.

Detailed design

This proposal takes the form of a diff to the existing compilation units ([§13.2](#)) section of the specification.

Diff

~~A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of zero or more *using_directives* followed by zero or more *global_attributes* followed by zero or more *namespace_member_declarations*.~~

A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of zero or more *using_directives* followed by zero or more *global_attributes* followed by a *compilation_unit_body*. A *compilation_unit_body* can either be a *file_scoped_namespace_declaration* or zero or more *statements* and *namespace_member_declarations*.

```
antlr
```

```
compilation_unit
~~    : extern_alias_directive* using_directive* global_attributes?
namespace_member_declaration*~~
      : extern_alias_directive* using_directive* global_attributes?
compilation_unit_body
      ;

compilation_unit_body
      : statement* namespace_member_declaration*
      | file_scoped_namespace_declaration
      ;
```

... unchanged ...

A *file_scoped_namespace_declaration* will contribute members corresponding to the *namespace_declaration* it is semantically equivalent to. See ([Namespace Declarations](#)) for more details.

Namespace declarations

A *namespace_declaration* consists of the keyword `namespace`, followed by a namespace name and body, optionally followed by a semicolon. A

file_scoped_namespace_declaration consists of the keyword `namespace`, followed by a namespace name, a semicolon and an optional list of *extern_alias_directives*, *using_directives* and *type_declarations*.

```
antlr
```

```
namespace_declaration
```

```
    : 'namespace' qualified_identifier namespace_body ';'?
```

```
    ;
```

```
file_scoped_namespace_declaration
```

```
    : 'namespace' qualified_identifier ';' extern_alias_directive*  
    using_directive* type_declaration*
```

```
    ;
```

```
... unchanged ...
```

... unchanged ...

the two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `N1.N2.A` and `N1.N2.B`. Because the two declarations contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

A *file_scoped_namespace_declaration* permits a namespace declaration to be written without the `{ ... }` block. For example:

```
C#
```

```
extern alias A;
```

```
namespace Name;
```

```
using B;
```

```
class C
```

```
{
```

```
}
```

is semantically equivalent to

C#

```
extern alias A;
namespace Name
{
    using B;
    class C
    {
    }
}
```

Specifically, a *file_scoped_namespace_declaration* is treated the same as a *namespace_declaration* at the same location in the *compilation_unit* with the same *qualified_identifier*. The *extern_alias_directives*, *using_directives* and *type_declarations* of that *file_scoped_namespace_declaration* act as if they were declared in the same order inside the *namespace_body* of that *namespace_declaration*.

A source file cannot contain both a *file_scoped_namespace_declaration* and a *namespace_declaration*. A source file cannot contain multiple *file_scoped_namespace_declarations*. A *compilation_unit* cannot contain both a *file_scoped_namespace_declaration* and any top level *statements*. *type_declarations* cannot precede a *file_scoped_namespace_declaration*.

Extern aliases

... unchanged ...

Extended property patterns

Article • 2021-09-21 • 2 minutes to read

Summary

Allow property subpatterns to reference nested members, for instance:

C#

```
if (e is MethodCallExpression { Method.Name: "MethodName" })
```

Instead of:

C#

```
if (e is MethodCallExpression { Method: { Name: "MethodName" } })
```

Motivation

When you want to match a child property, nesting another recursive pattern adds too much noise which will hurt readability with no real advantage.

Detailed design

The [property_pattern](#) syntax is modified as follow:

diff

```
property_pattern
: type? property_pattern_clause simple_designation?
;
```

```
property_pattern_clause
: '{' (subpattern (',' subpattern)* ','?)? '}'
;
```

```
subpattern
- : identifier ':' pattern
+ : subpattern_name ':' pattern
;
```

```
+subpattern_name
+ : identifier
```

```
+ | subpattern_name '.' identifier  
+ ;
```

The receiver for each name lookup is the type of the previous member T_0 , starting from the *input type* of the *property_pattern*. if T is a nullable type, T_0 is its underlying type, otherwise T_0 is equal to T .

For example, a pattern of the form `{ Prop1.Prop2: pattern }` is exactly equivalent to `{ Prop1: { Prop2: pattern } }`.

Note that this will include the null check when T is a nullable value type or a reference type. This null check means that the nested properties available will be the properties of T_0 , not of T .

Repeated member paths are allowed. The compilation of pattern matching can take advantage of common parts of patterns.

Improved Interpolated Strings

Article • 2022-03-21 • 29 minutes to read

Summary

We introduce a new pattern for creating and using interpolated string expressions to allow for efficient formatting and use in both general `string` scenarios and more specialized scenarios such as logging frameworks, without incurring unnecessary allocations from formatting the string in the framework.

Motivation

Today, string interpolation mainly lowers down to a call to `string.Format`. This, while general purpose, can be inefficient for a number of reasons:

1. It boxes any struct arguments, unless the runtime has happened to introduce an overload of `string.Format` that takes exactly the correct types of arguments in exactly the correct order.
 - This ordering is why the runtime is hesitant to introduce generic versions of the method, as it would lead to combinatoric explosion of generic instantiations of a very common method.
2. It has to allocate an array for the arguments in most cases.
3. There is no opportunity to avoid instantiating the instance if it's not needed. Logging frameworks, for example, will recommend avoiding string interpolation because it will cause a string to be realized that may not be needed, depending on the current log-level of the application.
4. It can never use `Span` or other ref struct types today, because ref structs are not allowed as generic type parameters, meaning that if a user wants to avoid copying to intermediate locations they have to manually format strings.

Internally, the runtime has a type called `ValueStringBuilder` to help deal with the first 2 of these scenarios. They pass a stackalloc'd buffer to the builder, repeatedly call `AppendFormat` with every part, and then get a final string out. If the resulting string goes past the bounds of the stack buffer, they can then move to an array on the heap. However, this type is dangerous to expose directly, as incorrect usage could lead to a rented array to be double-disposed, which then will cause all sorts of undefined behavior in the program as two locations think they have sole access to the rented array.

This proposal creates a way to use this type safely from native C# code by just writing an interpolated string literal, leaving written code unchanged while improving every interpolated string that a user writes. It also extends this pattern to allow for interpolated strings passed as arguments to other methods to use a handler pattern, defined by receiver of the method, that will allow things like logging frameworks to avoid allocating strings that will never be needed, and giving C# users familiar, convenient interpolation syntax.

Detailed Design

The handler pattern

We introduce a new handler pattern that can represent an interpolated string passed as an argument to a method. The simple English of the pattern is as follows:

When an *interpolated_string_expression* is passed as an argument to a method, we look at the type of the parameter. If the parameter type has a constructor that can be invoked with 2 int parameters, `literalLength` and `formattedCount`, optionally takes additional parameters specified by an attribute on the original parameter, optionally has an out boolean trailing parameter, and the type of the original parameter has instance `AppendLiteral` and `AppendFormatted` methods that can be invoked for every part of the interpolated string, then we lower the interpolation using that, instead of into a traditional call to `string.Format(formatStr, args)`. A more concrete example is helpful for picturing this:

C#

```
// The handler that will actually "build" the interpolated string
[InterpolatedStringHandler]
public ref struct TraceLoggerParamsInterpolatedStringHandler
{
    // Storage for the built-up string

    private bool _logLevelEnabled;

    public TraceLoggerParamsInterpolatedStringHandler(int literalLength, int
formattedCount, Logger logger, out bool handlerIsValid)
    {
        if (!logger._logLevelEnabled)
        {
            handlerIsValid = false;
            return;
        }

        handlerIsValid = true;
    }
}
```

```

        _logLevelEnabled = logger.EnabledLevel;
    }

    public void AppendLiteral(string s)
    {
        // Store and format part as required
    }

    public void AppendFormatted<T>(T t)
    {
        // Store and format part as required
    }
}

// The logger class. The user has an instance of this, accesses it via
// static state, or some other access
// mechanism
public class Logger
{
    // Initialization code omitted
    public LogLevel EnabledLevel;

    public void
    LogTrace([InterpolatedStringHandlerArguments("")]TraceLoggerParamsInterpolat
    edStringHandler handler)
    {
        // Impl of logging
    }
}

Logger logger = GetLogger(LogLevel.Info);

// Given the above definitions, usage looks like this:
var name = "Fred Silberberg";
logger.LogTrace($"{name} will never be printed because info is < trace!");

// This is converted to:
var name = "Fred Silberberg";
var receiverTemp = logger;
var handler = new TraceLoggerParamsInterpolatedStringHandler(literalLength:
47, formattedCount: 1, receiverTemp, out var handlerIsValid);
if (handlerIsValid)
{
    handler.AppendFormatted(name);
    handler.AppendLiteral(" will never be printed because info is <
trace!");
}
receiverTemp.LogTrace(handler);

```

Here, because `TraceLoggerParamsInterpolatedStringHandler` has a constructor with the correct parameters, we say that the interpolated string has an implicit handler conversion to that parameter, and it lowers to the pattern shown above. The specese needed for this is a bit complicated, and is expanded below.

The rest of this proposal will use `Append...` to refer to either of `AppendLiteral` or `AppendFormatted` in cases when both are applicable.

New attributes

The compiler recognizes the

`System.Runtime.CompilerServices.InterpolatedStringHandlerAttribute`:

C#

```
using System;
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Class | AttributeTargets.Struct,
        AllowMultiple = false, Inherited = false)]
    public sealed class InterpolatedStringHandlerAttribute : Attribute
    {
        public InterpolatedStringHandlerAttribute()
        {
        }
    }
}
```

This attribute is used by the compiler to determine if a type is a valid interpolated string handler type.

The compiler also recognizes the

`System.Runtime.CompilerServices.InterpolatedStringHandlerArgumentAttribute`:

C#

```
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Parameter, AllowMultiple = false,
        Inherited = false)]
    public sealed class InterpolatedStringHandlerArgumentAttribute :
        Attribute
    {
        public InterpolatedHandlerArgumentAttribute(string argument);
        public InterpolatedHandlerArgumentAttribute(params string[]
arguments);

        public string[] Arguments { get; }
    }
}
```

This attribute is used on parameters, to inform the compiler how to lower an interpolated string handler pattern used in a parameter position.

Interpolated string handler conversion

Type `T` is said to be an *applicable_interpolated_string_handler_type* if it is attributed with `System.Runtime.CompilerServices.InterpolatedStringHandlerAttribute`. There exists an implicit *interpolated_string_handler_conversion* to `T` from an *interpolated_string_expression*, or an *additive_expression* composed entirely of *_interpolated_string_expression_s* and using only `+` operators.

For simplicity in the rest of this speclet, *interpolated_string_expression* refers to both a simple *interpolated_string_expression*, and to an *additive_expression* composed entirely of *_interpolated_string_expression_s* and using only `+` operators.

Note that this conversion always exists, regardless of whether there will be later errors when actually attempting to lower the interpolation using the handler pattern. This is done to help ensure that there are predictable and useful errors and that runtime behavior doesn't change based on the content of an interpolated string.

Applicable function member adjustments

We adjust the wording of the applicable function member algorithm ([§11.6.4.2](#)) as follows (a new sub-bullet is added to each section, in bold):

A function member is said to be an *applicable function member* with respect to an argument list `A` when all of the following are true:

- Each argument in `A` corresponds to a parameter in the function member declaration as described in Corresponding parameters ([§11.6.2.2](#)), and any parameter to which no argument corresponds is an optional parameter.
- For each argument in `A`, the parameter passing mode of the argument (i.e., `value`, `ref`, or `out`) is identical to the parameter passing mode of the corresponding parameter, and
 - for a `value` parameter or a parameter array, an implicit conversion ([§10.2](#)) exists from the argument to the type of the corresponding parameter, or
 - for a `ref` parameter whose type is a struct type, an implicit *interpolated_string_handler_conversion* exists from the argument to the type of the corresponding parameter, or
 - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter. After all, a `ref` or `out` parameter is an alias for the argument passed.

For a function member that includes a parameter array, if the function member is applicable by the above rules, it is said to be applicable in its *normal form*. If a function

member that includes a parameter array is not applicable in its normal form, the function member may instead be applicable in its *expanded form*:

- The expanded form is constructed by replacing the parameter array in the function member declaration with zero or more value parameters of the element type of the parameter array such that the number of arguments in the argument list `A` matches the total number of parameters. If `A` has fewer arguments than the number of fixed parameters in the function member declaration, the expanded form of the function member cannot be constructed and is thus not applicable.
- Otherwise, the expanded form is applicable if for each argument in `A` the parameter passing mode of the argument is identical to the parameter passing mode of the corresponding parameter, and
 - for a fixed value parameter or a value parameter created by the expansion, an implicit conversion (§10.2) exists from the type of the argument to the type of the corresponding parameter, or
 - for a `ref` parameter whose type is a struct type, an implicit *interpolated_string_handler_conversion* exists from the argument to the type of the corresponding parameter, or
 - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter.

Important note: this means that if there are 2 otherwise equivalent overloads, that only differ by the type of the *applicable_interpolated_string_handler_type*, these overloads will be considered ambiguous. Further, because we do not see through explicit casts, it is possible that there could arise an unresolvable scenario where both applicable overloads use `InterpolatedStringHandlerArguments` and are totally uncallable without manually performing the handler lowering pattern. We could potentially make changes to the better function member algorithm to resolve this if we so choose, but this scenario unlikely to occur and isn't a priority to address.

Better conversion from expression adjustments

We change the better conversion from expression (§11.6.4.4) section to the following:

Given an implicit conversion `c1` that converts from an expression `E` to a type `T1`, and an implicit conversion `c2` that converts from an expression `E` to a type `T2`, `c1` is a *better conversion* than `c2` if:

1. `E` is a non-constant *interpolated_string_expression*, `c1` is an *implicit_string_handler_conversion*, `T1` is an

applicable_interpolated_string_handler_type, and `c2` is not an *implicit_string_handler_conversion*, or

2. `E` does not exactly match `T2` and at least one of the following holds:

- `E` exactly matches `T1` ([§11.6.4.4](#))
- `T1` is a better conversion target than `T2` ([§11.6.4.6](#))

This does mean that there are some potentially non-obvious overload resolution rules, depending on whether the interpolated string in question is a constant-expression or not. For example:

C#

```
void Log(string s) { ... }
void Log(TraceLoggerParamsInterpolatedStringHandler p) { ... }

Log(""); // Calls Log(string s), because "" is a constant expression
Log($"{test}"); // Calls Log(string s), because $"{test}" is a constant
expression
Log($"{1}"); // Calls Log(TraceLoggerParamsInterpolatedStringHandler p),
because $"{1}" is not a constant expression
```

This is introduced so that things that can simply be emitted as constants do so, and don't incur any overhead, while things that cannot be constant use the handler pattern.

InterpolatedStringHandler and Usage

We introduce a new type in `System.Runtime.CompilerServices`:

`DefaultInterpolatedStringHandler`. This is a ref struct with many of the same semantics as `ValueStringBuilder`, intended for direct use by the C# compiler. This struct would look approximately like this:

C#

```
// API Proposal issue: https://github.com/dotnet/runtime/issues/50601
namespace System.Runtime.CompilerServices
{
    [InterpolatedStringHandler]
    public ref struct DefaultInterpolatedStringHandler
    {
        public DefaultInterpolatedStringHandler(int literalLength, int
formattedCount);
        public string ToStringAndClear();

        public void AppendLiteral(string value);

        public void AppendFormatted<T>(T value);
    }
}
```

```

    public void AppendFormatted<T>(T value, string? format);
    public void AppendFormatted<T>(T value, int alignment);
    public void AppendFormatted<T>(T value, int alignment, string?
format);

    public void AppendFormatted(ReadOnlySpan<char> value);
    public void AppendFormatted(ReadOnlySpan<char> value, int alignment
= 0, string? format = null);

    public void AppendFormatted(string? value);
    public void AppendFormatted(string? value, int alignment = 0,
string? format = null);

    public void AppendFormatted(object? value, int alignment = 0,
string? format = null);
    }
}

```

We make a slight change to the rules for the meaning of an *interpolated_string_expression* (§11.7.3 [↗](#)):

If the type of an interpolated string is `string` and the type

`System.Runtime.CompilerServices.DefaultInterpolatedStringHandler` exists, and the current context supports using that type, the string is lowered using the handler pattern. The final `string` value is then obtained by calling `TostringAndClear()` on the handler type. Otherwise, if the type of an interpolated string is `System.IFormattable` or `System.FormattableString` [the rest is unchanged]

The "and the current context supports using that type" rule is intentionally vague to give the compiler leeway in optimizing usage of this pattern. The handler type is likely to be a ref struct type, and ref struct types are normally not permitted in async methods. For this particular case, the compiler would be allowed to make use the handler if none of the interpolation holes contain an `await` expression, as we can statically determine that the handler type is safely used without additional complicated analysis because the handler will be dropped after the interpolated string expression is evaluated.

Open Question:

Do we want to instead just make the compiler know about `DefaultInterpolatedStringHandler` and skip the `string.Format` call entirely? It would allow us to hide a method that we don't necessarily want to put in people's faces when they manually call `string.Format`.

Answer: Yes.

Open Question:

Do we want to have handlers for `System.IFormattable` and `System.FormattableString` as well?

Answer: No.

Handler pattern codegen

In this section, method invocation resolution refers to the steps listed in [§11.7.8.2](#).

Constructor resolution

Given an *applicable_interpolated_string_handler_type* `T` and an *interpolated_string_expression* `i`, method invocation resolution and validation for a valid constructor on `T` is performed as follows:

1. Member lookup for instance constructors is performed on `T`. The resulting method group is called `M`.
2. The argument list `A` is constructed as follows:
 - a. The first two arguments are integer constants, representing the literal length of `i`, and the number of *interpolation* components in `i`, respectively.
 - b. If `i` is used as an argument to some parameter `pi` in method `M1`, and parameter `pi` is attributed with `System.Runtime.CompilerServices.InterpolatedStringHandlerArgumentAttribute`, then for every name `Argx` in the `Arguments` array of that attribute the compiler matches it to a parameter `px` that has the same name. The empty string is matched to the receiver of `M1`.
 - If any `Argx` is not able to be matched to a parameter of `M1`, or an `Argx` requests the receiver of `M1` and `M1` is a static method, an error is produced and no further steps are taken.
 - Otherwise, the type of every resolved `px` is added to the argument list, in the order specified by the `Arguments` array. Each `px` is passed with the same `ref` semantics as is specified in `M1`.
 - c. The final argument is a `bool`, passed as an `out` parameter.
3. Traditional method invocation resolution is performed with method group `M` and argument list `A`. For the purposes of method invocation final validation, the context of `M` is treated as a *member_access* through type `T`.

- If a single-best constructor `F` was found, the result of overload resolution is `F`.
- If no applicable constructors were found, step 3 is retried, removing the final `bool` parameter from `A`. If this retry also finds no applicable members, an error is produced and no further steps are taken.
- If no single-best method was found, the result of overload resolution is ambiguous, an error is produced, and no further steps are taken.

4. Final validation on `F` is performed.

- If any element of `A` occurred lexically after `i`, an error is produced and no further steps are taken.
- If any `A` requests the receiver of `F`, and `F` is an indexer being used as an *initializer_target* in a *member_initializer*, then an error is reported and no further steps are taken.

Note: the resolution here intentionally do *not* use the actual expressions passed as other arguments for `Argx` elements. We only consider the types post-conversion. This makes sure that we don't have double-conversion issues, or unexpected cases where a lambda is bound to one delegate type when passed to `M1` and bound to a different delegate type when passed to `M`.

Note: We report an error for indexers uses as member initializers because of the order of evaluation for nested member initializers. Consider this code snippet:

C#

```
var x1 = new C1 { C2 = { [GetString()] = { A = 2, B = 4 } } };

/* Lowering:
__c1 = new C1();
string argTemp = GetString();
__c1.C2[argTemp][1] = 2;
__c1.C2[argTemp][3] = 4;

Prints:
GetString
get_C2
get_C2
*/

string GetString()
{
    Console.WriteLine("GetString");
    return "";
}
```

```

class C1
{
    private C2 c2 = new C2();
    public C2 C2 { get { Console.WriteLine("get_C2"); return c2; } set { } }
}

class C2
{
    public C3 this[string s]
    {
        get => new C3();
        set { }
    }
}

class C3
{
    public int A
    {
        get => 0;
        set { }
    }
    public int B
    {
        get => 0;
        set { }
    }
}

```

The arguments to `__c1.C2[]` are evaluated *before* the receiver of the indexer. While we could come up with a lowering that works for this scenario (either by creating a temp for `__c1.C2` and sharing it across both indexer invocations, or only using it for the first indexer invocation and sharing the argument across both invocations) we think that any lowering would be confusing for what we believe is a pathological scenario. Therefore, we forbid the scenario entirely.

Open Question:

If we use a constructor instead of `Create`, we'd improve runtime codegen, at the expense of narrowing the pattern a bit.

Answer: We will restrict to constructors for now. We can revisit adding a general `Create` method later if the scenario arises.

Append... method overload resolution

Given an *applicable_interpolated_string_handler_type* `T` and an *interpolated_string_expression* `i`, overload resolution for a set of valid `Append...` methods on `T` is performed as follows:

1. If there are any *interpolated_regular_string_character* components in `i`:
 - a. Member lookup on `T` with the name `AppendLiteral` is performed. The resulting method group is called `ML`.
 - b. The argument list `AL` is constructed with one value parameter of type `string`.
 - c. Traditional method invocation resolution is performed with method group `ML` and argument list `AL`. For the purposes of method invocation final validation, the context of `ML` is treated as a *member_access* through an instance of `T`.
 - If a single-best method `Fi` is found and no errors were produced, the result of method invocation resolution is `Fi`.
 - Otherwise, an error is reported.
2. For every *interpolation* `ix` component of `i`:
 - a. Member lookup on `T` with the name `AppendFormatted` is performed. The resulting method group is called `MF`.
 - b. The argument list `AF` is constructed:
 - i. The first parameter is the *expression* of `ix`, passed by value.
 - ii. If `ix` directly contains a *constant_expression* component, then an integer value parameter is added, with the name `alignment` specified.
 - iii. If `ix` is directly followed by an *interpolation_format*, then a string value parameter is added, with the name `format` specified.
 - c. Traditional method invocation resolution is performed with method group `MF` and argument list `AF`. For the purposes of method invocation final validation, the context of `MF` is treated as a *member_access* through an instance of `T`.
 - If a single-best method `Fi` is found, the result of method invocation resolution is `Fi`.
 - Otherwise, an error is reported.
3. Finally, for every `Fi` discovered in steps 1 and 2, final validation is performed:
 - If any `Fi` does not return `bool` by value or `void`, an error is reported.
 - If all `Fi` do not return the same type, an error is reported.

Note that these rules do not permit extension methods for the `Append...` calls. We could consider enabling that if we choose, but this is analogous to the enumerator

pattern, where we allow `GetEnumerator` to be an extension method, but not `Current` or `MoveNext()`.

These rules *do* permit default parameters for the `Append...` calls, which will work with things like `CallerLineNumber` or `CallerArgumentExpression` (when supported by the language).

We have separate overload lookup rules for base elements vs interpolation holes because some handlers will want to be able to understand the difference between the components that were interpolated and the components that were part of the base string.

Open Question

Some scenarios, like structured logging, want to be able to provide names for interpolation elements. For example, today a logging call might look like `Log("{name} bought {itemCount} items", name, items.Count);`. The names inside the `{}` provide important structure information for loggers that help with ensuring output is consistent and uniform. Some cases might be able to reuse the `:format` component of an interpolation hole for this, but many loggers already understand format specifiers and have existing behavior for output formatting based on this info. Is there some syntax we can use to enable putting these named specifiers in?

Some cases may be able to get away with `CallerArgumentExpression`, provided that support does land in C# 10. But for cases that invoke a method/property, that may not be sufficient.

Answer:

While there are some interesting parts to templated strings we could explore in an orthogonal language feature, we don't think a specific syntax here has much benefit over solutions such as using a tuple: `$"({ "StructuredCategory", myExpression })"`.

Performing the conversion

Given an *applicable_interpolated_string_handler_type* `T` and an *interpolated_string_expression* `i` that had a valid constructor `Fc` and `Append...` methods `Fa` resolved, lowering for `i` is performed as follows:

1. Any arguments to `Fc` that occur lexically before `i` are evaluated and stored into temporary variables in lexical order. In order to preserve lexical ordering, if `i`

- occurred as part of a larger expression `e`, any components of `e` that occurred before `i` will be evaluated as well, again in lexical order.
2. `Fc` is called with the length of the interpolated string literal components, the number of *interpolation* holes, any previously evaluated arguments, and a `bool` out argument (if `Fc` was resolved with one as the last parameter). The result is stored into a temporary value `ib`.
 - a. The length of the literal components is calculated after replacing any *open_brace_escape_sequence* with a single `{`, and any *close_brace_escape_sequence* with a single `}`.
 3. If `Fc` ended with a `bool` out argument, a check on that `bool` value is generated. If true, the methods in `Fa` will be called. Otherwise, they will not be called.
 4. For every `Fax` in `Fa`, `Fax` is called on `ib` with either the current literal component or *interpolation* expression, as appropriate. If `Fax` returns a `bool`, the result is logically anded with all preceding `Fax` calls.
 - a. If `Fax` is a call to `AppendLiteral`, the literal component is unescaped by replacing any *open_brace_escape_sequence* with a single `{`, and any *close_brace_escape_sequence* with a single `}`.
 5. The result of the conversion is `ib`.

Again, note that arguments passed to `Fc` and arguments passed to `e` are the same temp. Conversions may occur on top of the temp to convert to a form that `Fc` requires, but for example lambdas cannot be bound to a different delegate type between `Fc` and `e`.

Open Question

This lowering means that subsequent parts of the interpolated string after a false-returning `Append...` call don't get evaluated. This could potentially be very confusing, particularly if the format hole is side-effecting. We could instead evaluate all format holes first, then repeatedly call `Append...` with the results, stopping if it returns false. This would ensure that all expressions get evaluated as one might expect, but we call as few methods as we need to. While the partial evaluation might be desirable for some more advanced cases, it is perhaps non-intuitive for the general case.

Another alternative, if we want to always evaluate all format holes, is to remove the `Append...` version of the API and just do repeated `Format` calls. The handler can track whether it should just be dropping the argument and immediately returning for this version.

Answer: We will have conditional evaluation of the holes.

Open Question

Do we need to dispose of disposable handler types, and wrap calls with try/finally to ensure that Dispose is called? For example, the interpolated string handler in the bcl might have a rented array inside it, and if one of the interpolation holes throws an exception during evaluation, that rented array could be leaked if it wasn't disposed.

Answer: No. handlers can be assigned to locals (such as `MyHandler handler = $" {MyCode()} ;`), and the lifetime of such handlers is unclear. Unlike foreach enumerators, where the lifetime is obvious and no user-defined local is created for the enumerator.

Impact on nullable reference types

To minimize complexity of the implementation, we have a few limitations on how we perform nullable analysis on interpolated string handler constructors used as arguments to a method or indexer. In particular, we do not flow information from the constructor back through to the original slots of parameters or arguments from the original context, and we do not use constructor parameter types to inform generic type inference for type parameters in the containing method. An example of where this can have an impact is:

C#

```
string s = "";
C c = new C();
c.M(s, $"{s}", c.ToString(), s.ToString()); // No warnings on c.ToString() or
s.ToString(), as the `MaybeNull` does not flow back.

public class C
{
    public void M(string s1, [InterpolatedStringHandlerArgument("", "s1")]
CustomHandler c1, string s2, string s3) { }
}

[InterpolatedStringHandler]
public partial struct CustomHandler
{
    public CustomHandler(int literalLength, int formattedCount, [MaybeNull]
C c, [MaybeNull] string s) : this()
    {
    }
}
```

C#

```
string? s = null;
M(s, $"{s}"); // Infers `string` for `T` because of the `T?` parameter, not
```

``string?``, as flow analysis does not consider the unannotated ``T`` parameter of the constructor

```
void M<T>(T? t, [InterpolatedStringHandlerArgument("s1")] CustomHandler<T>
c) { }
```

```
[InterpolatedStringHandler]
public partial struct CustomHandler<T>
{
    public CustomHandler(int literalLength, int formattedCount, T t) :
    this()
    {
    }
}
```

Other considerations

Allow `string` types to be convertible to handlers as well

For type author simplicity, we could consider allowing expressions of type `string` to be implicitly-convertible to *applicable_interpolated_string_handler_types*. As proposed today, authors will likely need to overload on both that handler type and regular `string` types, so their users don't have to understand the difference. This may be an annoying and non-obvious overhead, as a `string` expression can be viewed as an interpolation with `expression.Length` prefilled length and 0 holes to be filled.

This would allow new APIs to only expose a handler, without also having to expose a `string`-accepting overload. However, it won't get around the need for changes to better conversion from expression, so while it would work it may be unnecessary overhead.

Answer:

We think that this could end up being confusing, and there's an easy workaround for custom handler types: add a user-defined conversion from string.

Incorporating spans for heap-less strings

`ValueStringBuilder` as it exists today has 2 constructors: one that takes a count, and allocates on the heap eagerly, and one that takes a `Span<char>`. That `Span<char>` is usually a fixed size in the runtime codebase, around 250 elements on average. To truly replace that type, we should consider an extension to this where we also recognize

`GetInterpolatedString` methods that take a `Span<char>`, instead of just the count version. However, we see a few potential thorny cases to resolve here:

- We don't want to `stackalloc` repeatedly in a hot loop. If we were to do this extension to the feature, we'd likely want to share the `stackalloc`'d span between loop iterations. We know this is safe, as `Span<T>` is a ref struct that can't be stored on the heap, and users would have to be pretty devious to manage to extract a reference to that `Span` (such as creating a method that accepts such a handler then deliberately retrieving the `Span` from the handler and returning it to the caller). However, allocating ahead of time produces other questions:
 - Should we eagerly `stackalloc`? What if the loop is never entered, or exits before it needs the space?
 - If we don't eagerly `stackalloc`, does that mean we introduce a hidden branch on every loop? Most loops likely won't care about this, but it could affect some tight loops that don't want to pay the cost.
- Some strings can be quite big, and the appropriate amount to `stackalloc` is dependent on a number of factors, including runtime factors. We don't really want the C# compiler and specification to have to determine this ahead of time, so we'd want to resolve <https://github.com/dotnet/runtime/issues/25423> and add an API for the compiler to call in these cases. It also adds more pros and cons to the points from the previous loop, where we don't want to potentially allocate large arrays on the heap many times or before one is needed.

Answer:

This is out of scope for C# 10. We can look at this in general when we look at the more general `params Span<T>` feature.

Non-try version of the API

For simplicity, this spec currently just proposes recognizing a `Append...` method, and things that always succeed (like `InterpolatedStringHandler`) would always return true from the method. This was done to support partial formatting scenarios where the user wants to stop formatting if an error occurs or if it's unnecessary, such as the logging case, but could potentially introduce a bunch of unnecessary branches in standard interpolated string usage. We could consider an addendum where we use just `FormatX` methods if no `Append...` method is present, but it does present questions about what we do if there's a mix of both `Append...` and `FormatX` calls.

Answer:

We want the non-try version of the API. The proposal has been updated to reflect this.

Passing previous arguments to the handler

There is unfortunate lack of symmetry in the proposal as it currently exists: invoking an extension method in reduced form produces different semantics than invoking the extension method in normal form. This is different from most other locations in the language, where reduced form is just a sugar. We propose adding an attribute to the framework that we will recognize when binding a method, that informs the compiler that certain parameters should be passed to the constructor on the handler. Usage looks like this:

C#

```
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Parameter, AllowMultiple = false,
    Inherited = false)]
    public sealed class InterpolatedStringHandlerArgumentAttribute :
    Attribute
    {
        public InterpolatedStringHandlerArgumentAttribute(string argument);
        public InterpolatedStringHandlerArgumentAttribute(params string[]
arguments);

        public string[] Arguments { get; }
    }
}
```

Usage of this is then:

C#

```
namespace System
{
    public sealed class String
    {
        public static string Format(IFormatProvider? provider,
[InterpolatedStringHandlerArgument("provider")] ref
DefaultInterpolatedStringHandler handler);
        ...
    }
}

namespace System.Runtime.CompilerServices
{
    public ref struct DefaultInterpolatedStringHandler
    {
        public DefaultInterpolatedStringHandler(int baseLength, int
```

```

holeCount, IFormatProvider? provider); // additional factory
    ...
}
}

var formatted = string.Format(CultureInfo.InvariantCulture, $"{X} = {Y}");

// Is lowered to

var tmp1 = CultureInfo.InvariantCulture;
var handler = new DefaultInterpolatedStringHandler(3, 2, tmp1);
handler.AppendFormatted(X);
handler.AppendLiteral(" = ");
handler.AppendFormatted(Y);
var formatted = string.Format(tmp1, handler);

```

The questions we need to answer:

1. Do we like this pattern in general?
2. Do we want to allow these arguments to come from after the handler parameter?
Some existing patterns in the BCL, such as `Utf8Formatter`, put the value to be formatted *before* the thing needed to format into. To fit in best with these patterns, we'd likely want to allow this, but we need to decide if this out-of-order evaluate is ok.

Answer:

We want to support this. The spec has been updated to reflect this. Arguments will be required to be specified in lexical order at the call site, and if a needed argument to the create method is specified after the interpolated string literal, an error is produced.

await usage in interpolation holes

Because `($"{await A()}")` is a valid expression today, we need to rationalize how interpolation holes with `await`. We could solve this with a few rules:

1. If an interpolated string used as a `string`, `IFormattable`, or `FormattableString` has an `await` in an interpolation hole, fall back to old-style formatter.
2. If an interpolated string is subject to an *implicit_string_handler_conversion* and *applicable_interpolated_string_handler_type* is a `ref struct`, `await` is not allowed to be used in the format holes.

Fundamentally, this desugaring could use a `ref struct` in an `async` method as long as we guarantee that the `ref struct` will not need to be saved to the heap, which should be possible if we forbid `await`s in the interpolation holes.

Alternatively, we could simply make all handler types non-ref structs, including the framework handler for interpolated strings. This would, however, preclude us from someday recognizing a `Span` version that does not need to allocate any scratch space at all.

Answer:

We will treat interpolated string handlers the same as any other type: this means that if the handler type is a ref struct and the current context doesn't allow the usage of ref structs, it is illegal to use handler here. The spec around lowering of string literals used as strings is intentionally vague to allow the compiler to decide on what rules it deems appropriate, but for custom handler types they will have to follow the same rules as the rest of the language.

Handlers as ref parameters

Some handlers might want to be passed as ref parameters (either `in` or `ref`). Should we allow either? And if so, what will a `ref` handler look like? `ref $""` is confusing, as you're not actually passing the string by ref, you're passing the handler that is created from the ref by ref, and has similar potential issues with async methods.

Answer:

We want to support this. The spec has been updated to reflect this. The rules should reflect the same rules that apply to extension methods on value types.

Interpolated strings through binary expressions and conversions

Because this proposal makes interpolated strings context sensitive, we would like to allow the compiler to treat a binary expression composed entirely of interpolated strings, or an interpolated string subjected to a cast, as an interpolated string literal for the purposes of overload resolution. For example, take the following scenario:

C#

```
struct Handler1
{
    public Handler1(int literalLength, int formattedCount, C c) => ...;
    // AppendX... methods as necessary
}
struct Handler2
{
    public Handler2(int literalLength, int formattedCount, C c) => ...;
```

```

    // AppendX... methods as necessary
}

class C
{
    void M(Handler1 handler) => ...;
    void M(Handler2 handler) => ...;
}

c.M("${X}"); // Ambiguous between the M overloads

```

This would be ambiguous, necessitating a cast to either `Handler1` or `Handler2` in order to resolve. However, in making that cast, we would potentially throw away the information that there is context from the method receiver, meaning that the cast would fail because there is nothing to fill in the information of `c`. A similar issue arises with binary concatenation of strings: the user could want to format the literal across several lines to avoid line wrapping, but would not be able to because that would no longer be an interpolated string literal convertible to the handler type.

To resolve these cases, we make the following changes:

- An *additive_expression* composed entirely of *interpolated_string_expressions* and using only `+` operators is considered to be an *interpolated_string_literal* for the purposes of conversions and overload resolution. The final interpolated string is created by logically concatenating all individual *interpolated_string_expression* components, from left to right.
- A *cast_expression* or a *relational_expression* with operator `as` whose operand is an *interpolated_string_expressions* is considered an *interpolated_string_expressions* for the purposes of conversions and overload resolution.

Open Questions:

Do we want to do this? We don't do this for `System.FormatableString`, for example, but that can be broken out onto a different line, whereas this can be context-dependent and therefore not able to be broken out into a different line. There are also no overload resolution concerns with `FormattableString` and `IFormattable`.

Answer:

We think that this is a valid use case for additive expressions, but that the cast version is not compelling enough at this time. We can add it later if necessary. The spec has been updated to reflect this decision.

Other use cases

See <https://github.com/dotnet/runtime/issues/50635> for examples of proposed handler APIs using this pattern.

Constant Interpolated Strings

Article • 2022-08-24 • 3 minutes to read

Summary

Enables constants to be generated from interpolated strings of type string constant.

Motivation

The following code is already legal:

```
public class C
{
    const string S1 = "Hello world";
    const string S2 = "Hello" + " " + "World";
    const string S3 = S1 + " Kevin, welcome to the team!";
}
```

However, there have been many community requests to make the following also legal:

```
public class C
{
    const string S1 = $"Hello world";
    const string S2 = $"Hello{" "}World";
    const string S3 = $"{S1} Kevin, welcome to the team!";
}
```

This proposal represents the next logical step for constant string generation, where existing string syntax that works in other situations is made to work for constants.

Detailed design

The following represent the updated specifications for constant expressions under this new proposal. Current specifications from which this was directly based on can be found in [§11.20](#).

Constant Expressions

A `constant_expression` is an expression that can be fully evaluated at compile-time.

```
antlr
```

```
constant_expression  
    : expression  
    ;
```

A constant expression must be the `null` literal or a value with one of the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `object`, `string`, or any enumeration type. Only the following constructs are permitted in constant expressions:

- Literals (including the `null` literal).
- References to `const` members of class and struct types.
- References to members of enumeration types.
- References to `const` parameters or local variables
- Parenthesized sub-expressions, which are themselves constant expressions.
- Cast expressions, provided the target type is one of the types listed above.
- `checked` and `unchecked` expressions
- Default value expressions
- `Nameof` expressions
- The predefined `+`, `-`, `!`, and `~` unary operators.
- The predefined `+`, `-`, `*`, `/`, `%`, `<<`, `>>`, `&`, `|`, `^`, `&&`, `||`, `==`, `!=`, `<`, `>`, `<=`, and `>=` binary operators, provided each operand is of a type listed above.
- The `?:` conditional operator.
- *Interpolated strings `{}`, provided that all components are constant expressions of type `string` and all interpolated components lack alignment and format specifiers.*

The following conversions are permitted in constant expressions:

- Identity conversions
- Numeric conversions
- Enumeration conversions
- Constant expression conversions
- Implicit and explicit reference conversions, provided that the source of the conversions is a constant expression that evaluates to the null value.

Other conversions including boxing, unboxing and implicit reference conversions of non-null values are not permitted in constant expressions. For example:

```
C#
```

```
class C
{
    const object i = 5;           // error: boxing conversion not permitted
    const object str = "hello"; // error: implicit reference conversion
}
```

the initialization of `i` is an error because a boxing conversion is required. The initialization of `str` is an error because an implicit reference conversion from a non-null value is required.

Whenever an expression fulfills the requirements listed above, the expression is evaluated at compile-time. This is true even if the expression is a sub-expression of a larger expression that contains non-constant constructs.

The compile-time evaluation of constant expressions uses the same rules as run-time evaluation of non-constant expressions, except that where run-time evaluation would have thrown an exception, compile-time evaluation causes a compile-time error to occur.

Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur in integral-type arithmetic operations and conversions during the compile-time evaluation of the expression always cause compile-time errors ([§11.20](#)).

Constant expressions occur in the contexts listed below. In these contexts, a compile-time error occurs if an expression cannot be fully evaluated at compile-time.

- Constant declarations ([§14.4](#)).
- Enumeration member declarations ([§18.4](#)).
- Default arguments of formal parameter lists ([§14.6.2](#)).
- `case` labels of a `switch` statement ([§12.8.3](#)).
- `goto case` statements ([§12.10.4](#)).
- Dimension lengths in an array creation expression ([§11.7.15.5](#)) that includes an initializer.
- Attributes ([§21](#)).

An implicit constant expression conversion ([§10.2.11](#)) permits a constant expression of type `int` to be converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the constant expression is within the range of the destination type.

Drawbacks

This proposal adds additional complexity to the compiler in exchange for broader applicability of interpolated strings. As these strings are fully evaluated at compile time, the valuable automatic formatting features of interpolated strings are less necessary. Most use cases can be largely replicated through the alternatives below.

Alternatives

The current `+` operator for string concatenation can combine strings in a similar manner to the current proposal.

Unresolved questions

What parts of the design are still undecided?

Design meetings

Link to design notes that affect this proposal, and describe in one sentence for each what changes they led to.

Lambda improvements

Article • 2022-02-23 • 13 minutes to read

Summary

Proposed changes:

1. Allow lambdas with attributes
2. Allow lambdas with explicit return type
3. Infer a natural delegate type for lambdas and method groups

Motivation

Support for attributes on lambdas would provide parity with methods and local functions.

Support for explicit return types would provide symmetry with lambda parameters where explicit types can be specified. Allowing explicit return types would also provide control over compiler performance in nested lambdas where overload resolution must bind the lambda body currently to determine the signature.

A natural type for lambda expressions and method groups will allow more scenarios where lambdas and method groups may be used without an explicit delegate type, including as initializers in `var` declarations.

Requiring explicit delegate types for lambdas and method groups has been a friction point for customers, and has become an impediment to progress in ASP.NET with recent work on [MapAction](#).

[ASP.NET MapAction](#) without proposed changes (`MapAction()` takes a `System.Delegate` argument):

```
C#
```

```
[HttpGet("/")] Todo GetTodo() => new(Id: 0, Name: "Name");  
app.MapAction((Func<Todo>)GetTodo);  
  
[HttpPost("/")] Todo PostTodo([FromBody] Todo todo) => todo;  
app.MapAction((Func<Todo, Todo>)PostTodo);
```

[ASP.NET MapAction](#) with natural types for method groups:

C#

```
[HttpGet("/")] Todo GetTodo() => new(Id: 0, Name: "Name");
app.MapAction(GetTodo);

[HttpPost("/")] Todo PostTodo([FromBody] Todo todo) => todo;
app.MapAction(PostTodo);
```

[ASP.NET MapAction](#) with attributes and natural types for lambda expressions:

C#

```
app.MapAction([HttpGet("/")] () => new Todo(Id: 0, Name: "Name"));
app.MapAction([HttpPost("/")] ([FromBody] Todo todo) => todo);
```

Attributes

Attributes may be added to lambda expressions and lambda parameters. To avoid ambiguity between method attributes and parameter attributes, a lambda expression with attributes must use a parenthesized parameter list. Parameter types are not required.

C#

```
f = [A] () => { }; // [A] lambda
f = [return:A] x => x; // syntax error at '>'
f = [return:A] (x) => x; // [A] lambda
f = [A] static x => x; // syntax error at '>'

f = ([A] x) => x; // [A] x
f = ([A] ref int x) => x; // [A] x
```

Multiple attributes may be specified, either comma-separated within the same attribute list or as separate attribute lists.

C#

```
var f = [A1, A2][A3] () => { }; // ok
var g = ([A1][A2, A3] int x) => x; // ok
```

Attributes are not supported for *anonymous methods* declared with `delegate { }` syntax.

C#

```
f = [A] delegate { return 1; }; // syntax error at 'delegate'
f = delegate ([A] int x) { return x; }; // syntax error at '['
```

The parser will look ahead to differentiate a collection initializer with an element assignment from a collection initializer with a lambda expression.

C#

```
var y = new C { [A] = x }; // ok: y[A] = x
var z = new C { [A] x => x }; // ok: z[0] = [A] x => x
```

The parser will treat `?[` as the start of a conditional element access.

C#

```
x = b ? [A]; // ok
y = b ? [A] () => { } : z; // syntax error at '('
```

Attributes on the lambda expression or lambda parameters will be emitted to metadata on the method that maps to the lambda.

In general, customers should not depend on how lambda expressions and local functions map from source to metadata. How lambdas and local functions are emitted can, and has, changed between compiler versions.

The changes proposed here are targeted at the `Delegate` driven scenario. It should be valid to inspect the `MethodInfo` associated with a `Delegate` instance to determine the signature of the lambda expression or local function including any explicit attributes and additional metadata emitted by the compiler such as default parameters. This allows teams such as ASP.NET to make available the same behaviors for lambdas and local functions as ordinary methods.

Explicit return type

An explicit return type may be specified before the parenthesized parameter list.

C#

```
f = T () => default; // ok
f = short x => 1; // syntax error at '=>'
f = ref int (ref int x) => ref x; // ok
f = static void (_) => { }; // ok
f = async async (async async) => async; // ok?
```

The parser will look ahead to differentiate a method call `T()` from a lambda expression

```
T () => e.
```

Explicit return types are not supported for anonymous methods declared with `delegate` `{ }` syntax.

C#

```
f = delegate int { return 1; }; // syntax error
f = delegate int (int x) { return x; }; // syntax error
```

Method type inference should make an exact inference from an explicit lambda return type.

C#

```
static void F<T>(Func<T, T> f) { ... }
F(int (i) => i); // Func<int, int>
```

Variance conversions are not allowed from lambda return type to delegate return type (matching similar behavior for parameter types).

C#

```
Func<object> f1 = string () => null; // error
Func<object?> f2 = object () => x; // warning
```

The parser allows lambda expressions with `ref` return types within expressions without additional parentheses.

C#

```
d = ref int () => x; // d = (ref int () => x)
F(ref int () => x); // F((ref int () => x))
```

`var` cannot be used as an explicit return type for lambda expressions.

C#

```
class var { }

d = var (var v) => v; // error: contextual keyword 'var' cannot
// be used as explicit lambda return type
d = @var (var v) => v; // ok
d = ref var (ref var v) => ref v; // error: contextual keyword 'var' cannot
```

```
be used as explicit lambda return type
d = ref @var (ref var v) => ref v; // ok
```

Natural (function) type

An *anonymous function* expression (§11.16 ↗) (a *lambda expression* or an *anonymous method*) has a natural type if the parameters types are explicit and the return type is either explicit or can be inferred (see §11.6.3.13 ↗).

A *method group* has a natural type if all candidate methods in the method group have a common signature. (If the method group may include extension methods, the candidates include the containing type and all extension method scopes.)

The natural type of an anonymous function expression or method group is a *function_type*. A *function_type* represents a method signature: the parameter types and ref kinds, and return type and ref kind. Anonymous function expressions or method groups with the same signature have the same *function_type*.

Function_types are used in a few specific contexts only:

- implicit and explicit conversions
- method type inference (§11.6.3 ↗) and best common type (§11.6.3.15 ↗)
- `var` initializers

A *function_type* exists at compile time only: *function_types* do not appear in source or metadata.

Conversions

From a *function_type* `F` there are implicit *function_type* conversions:

- To a *function_type* `G` if the parameters and return types of `F` are variance-convertible to the parameters and return type of `G`
- To `System.MulticastDelegate` or base classes or interfaces of `System.MulticastDelegate`
- To `System.Linq.Expressions.Expression` or `System.Linq.Expressions.LambdaExpression`

Anonymous function expressions and method groups already have *conversions from expression* to delegate types and expression tree types (see anonymous function conversions §10.7 ↗ and method group conversions §10.8 ↗). Those conversions are sufficient for converting to strongly-typed delegate types and expression tree types. The

function_type conversions above add *conversions from type* to the base types only:

`System.MulticastDelegate`, `System.Linq.Expressions.Expression`, etc.

There are no conversions to a *function_type* from a type other than a *function_type*.

There are no explicit conversions for *function_types* since *function_types* cannot be referenced in source.

A conversion to `System.MulticastDelegate` or base type or interface realizes the anonymous function or method group as an instance of an appropriate delegate type. A conversion to `System.Linq.Expressions.Expression<TDelegate>` or base type realizes the lambda expression as an expression tree with an appropriate delegate type.

C#

```
Delegate d = delegate (object obj) { }; // Action<object>
Expression e = () => ""; // Expression<Func<string>>
object o = "".Clone; // Func<object>
```

Function_type conversions are not implicit or explicit standard conversions [§10.4](#) and are not considered when determining whether a user-defined conversion operator is applicable to an anonymous function or method group. From evaluation of user defined conversions [§10.5.3](#):

For a conversion operator to be applicable, it must be possible to perform a standard conversion ([§10.4](#)) from the source type to the operand type of the operator, and it must be possible to perform a standard conversion from the result type of the operator to the target type.

C#

```
class C
{
    public static implicit operator C(Delegate d) { ... }
}

C c;
c = () => 1; // error: cannot convert lambda expression to type 'C'
c = (C)(() => 2); // error: cannot convert lambda expression to type 'C'
```

A warning is reported for an implicit conversion of a method group to `object`, since the conversion is valid but perhaps unintentional.

C#

```
Random r = new Random();
object obj;
obj = r.NextDouble;           // warning: Converting method group to 'object'.
Did you intend to invoke the method?
obj = (object)r.NextDouble; // ok
```

Type inference

The existing rules for type inference are mostly unchanged (see [§11.6.3](#)). There are however a **couple of changes** below to specific phases of type inference.

First phase

The first phase ([§11.6.3.2](#)) allows an anonymous function to bind to T_i even if T_i is not a delegate or expression tree type (perhaps a type parameter constrained to `System.Delegate` for instance).

For each of the method arguments E_i :

- If E_i is an anonymous function and T_i is a delegate type or expression tree type, an *explicit parameter type inference* is made from E_i to T_i and an *explicit return type inference* is made from E_i to T_i .
- Otherwise, if E_i has a type U and x_i is a value parameter then a *lower-bound inference* is made from U to T_i .
- Otherwise, if E_i has a type U and x_i is a `ref` or `out` parameter then an *exact inference* is made from U to T_i .
- Otherwise, no inference is made for this argument.

Explicit return type inference

An *explicit return type inference* is made from an expression E to a type T in the following way:

- If E is an anonymous function with explicit return type U_r and T is a delegate type or expression tree type with return type V_r then an *exact inference* ([§11.6.3.9](#)) is made from U_r to V_r .

Fixing

Fixing ([§11.6.3.12](#)) ensures other conversions are preferred over *function_type* conversions. (Lambda expressions and method group expressions only contribute to lower bounds so handling of *function_types* is needed for lower bounds only.)

An *unfixed* type variable x_i with a set of bounds is *fixed* as follows:

- The set of *candidate types* U_j starts out as the set of all types in the set of bounds for x_i where **function types are ignored in lower bounds if there any types that are not function types.**
- We then examine each bound for x_i in turn: For each exact bound U of x_i all types U_j which are not identical to U are removed from the candidate set. For each lower bound U of x_i all types U_j to which there is *not* an implicit conversion from U are removed from the candidate set. For each upper bound U of x_i all types U_j from which there is *not* an implicit conversion to U are removed from the candidate set.
- If among the remaining candidate types U_j there is a unique type V from which there is an implicit conversion to all the other candidate types, then x_i is fixed to V .
- Otherwise, type inference fails.

Best common type

Best common type ([§11.6.3.15](#)) is defined in terms of type inference so the type inference changes above apply to best common type as well.

C#

```
var fs = new[] { (string s) => s.Length; (string s) => int.Parse(s) } //  
Func<string, int>[]
```

var

Anonymous functions and method groups with function types can be used as initializers in `var` declarations.

C#

```
var f1 = () => default;           // error: cannot infer type  
var f2 = x => x;                 // error: cannot infer type  
var f3 = () => 1;                // System.Func<int>  
var f4 = string () => null;      // System.Func<string>  
var f5 = delegate (object o) { }; // System.Action<object>
```

```

static void F1() { }
static void F1<T>(this T t) { }
static void F2(this string s) { }

var f6 = F1;    // error: multiple methods
var f7 = "".F1; // System.Action
var f8 = F2;    // System.Action<string>

```

Function types are not used in assignments to discards.

C#

```

d = () => 0; // ok
_ = () => 1; // error

```

Delegate types

The delegate type for the anonymous function or method group with parameter types `P1, ..., Pn` and return type `R` is:

- if any parameter or return value is not by value, or there are more than 16 parameters, or any of the parameter types or return are not valid type arguments (say, `(int* p) => { }`), then the delegate is a synthesized `internal` anonymous delegate type with signature that matches the anonymous function or method group, and with parameter names `arg1, ..., argn` or `arg` if a single parameter;
- if `R` is `void`, then the delegate type is `System.Action<P1, ..., Pn>`;
- otherwise the delegate type is `System.Func<P1, ..., Pn, R>`.

The compiler may allow more signatures to bind to `System.Action<>` and `System.Func<>` types in the future (if `ref struct` types are allowed type arguments for instance).

`modopt()` or `modreq()` in the method group signature are ignored in the corresponding delegate type.

If two anonymous functions or method groups in the same compilation require synthesized delegate types with the same parameter types and modifiers and the same return type and modifiers, the compiler will use the same synthesized delegate type.

Overload resolution

Better function member ([§11.6.4.3](#)) is updated to prefer members where none of the conversions and none of the type arguments involved inferred types from lambda

expressions or method groups.

Better function member

... Given an argument list A with a set of argument expressions $\{E_1, E_2, \dots, E_n\}$ and two applicable function members M_p and M_q with parameter types $\{P_1, P_2, \dots, P_n\}$ and $\{Q_1, Q_2, \dots, Q_n\}$, M_p is defined to be a **better function member** than M_q if

1. for each argument, the implicit conversion from E_x to P_x is not a *function_type_conversion*, and
 - M_p is a non-generic method or M_p is a generic method with type parameters $\{X_1, X_2, \dots, X_p\}$ and for each type parameter x_i the type argument is inferred from an expression or from a type other than a *function_type*, and
 - for at least one argument, the implicit conversion from E_x to Q_x is a *function_type_conversion*, or M_q is a generic method with type parameters $\{Y_1, Y_2, \dots, Y_q\}$ and for at least one type parameter y_i the type argument is inferred from a *function_type*, or
2. for each argument, the implicit conversion from E_x to Q_x is not better than the implicit conversion from E_x to P_x , and for at least one argument, the conversion from E_x to P_x is better than the conversion from E_x to Q_x .

Better conversion from expression ([§11.6.4.4](#)) is updated to prefer conversions that did not involve inferred types from lambda expressions or method groups.

Better conversion from expression

Given an implicit conversion C_1 that converts from an expression E to a type T_1 , and an implicit conversion C_2 that converts from an expression E to a type T_2 , C_1 is a **better conversion** than C_2 if:

1. C_1 is not a *function_type_conversion* and C_2 is a *function_type_conversion*, or
2. E is a non-constant *interpolated_string_expression*, C_1 is an *implicit_string_handler_conversion*, T_1 is an *applicable_interpolated_string_handler_type*, and C_2 is not an *implicit_string_handler_conversion*, or
3. E does not exactly match T_2 and at least one of the following holds:

- `E` exactly matches `T1` (§11.6.4.4 [↗](#))
- `T1` is a better conversion target than `T2` (§11.6.4.6 [↗](#))

Syntax

antlr

```

lambda_expression
  : modifier* identifier '=>' (block | expression)
  | attribute_list* modifier* type? lambda_parameters '=>' (block |
expression)
  ;

lambda_parameters
  : lambda_parameter
  | '(' (lambda_parameter (',' lambda_parameter)*)? ')'
  ;

lambda_parameter
  : identifier
  | attribute_list* modifier* type? identifier equals_value_clause?
  ;

```

Open issues

Should default values be supported for lambda expression parameters for completeness?

Should `System.Diagnostics.ConditionalAttribute` be disallowed on lambda expressions since there are few scenarios where a lambda expression could be used conditionally?

C#

```

([Conditional("DEBUG")] static (x, y) => Assert(x == y))(a, b); // ok?

```

Should the *function_type* be available from the compiler API, in addition to the resulting delegate type?

Currently, the inferred delegate type uses `System.Action<>` or `System.Func<>` when parameter and return types are valid type arguments *and* there are no more than 16 parameters, and if the expected `Action<>` or `Func<>` type is missing, an error is reported. Instead, should the compiler use `System.Action<>` or `System.Func<>` regardless of arity? And if the expected type is missing, synthesize a delegate type otherwise?

CallerArgumentExpression

Article • 2022-05-03 • 7 minutes to read

Summary

Allow developers to capture the expressions passed to a method, to enable better error messages in diagnostic/testing APIs and reduce keystrokes.

Motivation

When an assertion or argument validation fails, the developer wants to know as much as possible about where and why it failed. However, today's diagnostic APIs do not fully facilitate this. Consider the following method:

```
C#  
  
T Single<T>(this T[] array)  
{  
    Debug.Assert(array != null);  
    Debug.Assert(array.Length == 1);  
  
    return array[0];  
}
```

When one of the asserts fail, only the filename, line number, and method name will be provided in the stack trace. The developer will not be able to tell which assert failed from this information-- they will have to open the file and navigate to the provided line number to see what went wrong.

This is also the reason testing frameworks have to provide a variety of assert methods. With xUnit, `Assert.True` and `Assert.False` are not frequently used because they do not provide enough context about what failed.

While the situation is a bit better for argument validation because the names of invalid arguments are shown to the developer, the developer must pass these names to exceptions manually. If the above example were rewritten to use traditional argument validation instead of `Debug.Assert`, it would look like

```
C#  
  
T Single<T>(this T[] array)  
{
```

```

    if (array == null)
    {
        throw new ArgumentNullException(nameof(array));
    }

    if (array.Length != 1)
    {
        throw new ArgumentException("Array must contain a single element.",
        nameof(array));
    }

    return array[0];
}

```

Notice that `nameof(array)` must be passed to each exception, although it's already clear from context which argument is invalid.

Detailed design

In the above examples, including the string `"array != null"` or `"array.Length == 1"` in the assert message would help the developer determine what failed. Enter

`CallerArgumentExpression`: it's an attribute the framework can use to obtain the string associated with a particular method argument. We would add it to `Debug.Assert` like so

```

C#

public static class Debug
{
    public static void Assert(bool condition,
    [CallerArgumentExpression("condition")] string message = null);
}

```

The source code in the above example would stay the same. However, the code the compiler actually emits would correspond to

```

C#

T Single<T>(this T[] array)
{
    Debug.Assert(array != null, "array != null");
    Debug.Assert(array.Length == 1, "array.Length == 1");

    return array[0];
}

```

The compiler specially recognizes the attribute on `Debug.Assert`. It passes the string associated with the argument referred to in the attribute's constructor (in this case, `condition`) at the call site. When either assert fails, the developer will be shown the condition that was false and will know which one failed.

For argument validation, the attribute cannot be used directly, but can be made use of through a helper class:

```
C#

public static class Verify
{
    public static void Argument(bool condition, string message,
[CallerArgumentExpression("condition")] string conditionExpression = null)
    {
        if (!condition) throw new ArgumentException(message: message,
paramName: conditionExpression);
    }

    public static void InRange(int argument, int low, int high,
[CallerArgumentExpression("argument")] string argumentExpression =
null,
[CallerArgumentExpression("low")] string lowExpression = null,
[CallerArgumentExpression("high")] string highExpression = null)
    {
        if (argument < low)
        {
            throw new ArgumentOutOfRangeException(paramName:
argumentExpression,
message: $"{argumentExpression} ({argument}) cannot be less
than {lowExpression} ({low}).");
        }

        if (argument > high)
        {
            throw new ArgumentOutOfRangeException(paramName:
argumentExpression,
message: $"{argumentExpression} ({argument}) cannot be
greater than {highExpression} ({high}).");
        }
    }

    public static void NotNull<T>(T argument,
[CallerArgumentExpression("argument")] string argumentExpression = null)
    where T : class
    {
        if (argument == null) throw new ArgumentNullException(paramName:
argumentExpression);
    }
}

T Single<T>(this T[] array)
```

```

{
    Verify.NotNull(array); // paramName: "array"
    Verify.Argument(array.Length == 1, "Array must contain a single
element."); // paramName: "array.Length == 1"

    return array[0];
}

T ElementAt(this T[] array, int index)
{
    Verify.NotNull(array); // paramName: "array"
    // paramName: "index"
    // message: "index (-1) cannot be less than 0 (0).", or
    //           "index (6) cannot be greater than array.Length - 1 (5)."
    Verify.InRange(index, 0, array.Length - 1);

    return array[index];
}

```

A proposal to add such a helper class to the framework is underway at <https://github.com/dotnet/corefx/issues/17068>. If this language feature was implemented, the proposal could be updated to take advantage of this feature.

Extension methods

The `this` parameter in an extension method may be referenced by `CallerArgumentExpression`. For example:

```

C#

public static void ShouldBe<T>(this T @this, T expected,
[CallerArgumentExpression("this")] string thisExpression = null) {}

contestant.Points.ShouldBe(1337); // thisExpression: "contestant.Points"

```

`thisExpression` will receive the expression corresponding to the object before the dot. If it's called with static method syntax, e.g. `Ext.ShouldBe(contestant.Points, 1337)`, it will behave as if first parameter wasn't marked `this`.

There should always be an expression corresponding to the `this` parameter. Even if an instance of a class calls an extension method on itself, e.g. `this.Single()` from inside a collection type, the `this` is mandated by the compiler so `"this"` will get passed. If this rule is changed in the future, we can consider passing `null` or the empty string.

Extra details

- Like the other `Caller*` attributes, such as `CallerMemberName`, this attribute may only be used on parameters with default values.
- Multiple parameters marked with `CallerArgumentExpression` are permitted, as shown above.
- The attribute's namespace will be `System.Runtime.CompilerServices`.
- If `null` or a string that is not a parameter name (e.g. `"notAParameterName"`) is provided, the compiler will pass in an empty string.
- The type of the parameter `CallerArgumentExpressionAttribute` is applied to must have a standard conversion from `string`. This means no user-defined conversions from `string` are allowed, and in practice means the type of such a parameter must be `string`, `object`, or an interface implemented by `string`.

Drawbacks

- People who know how to use decompilers will be able to see some of the source code at call sites for methods marked with this attribute. This may be undesirable/unexpected for closed-source software.
- Although this is not a flaw in the feature itself, a source of concern may be that there exists a `Debug.Assert` API today that only takes a `bool`. Even if the overload taking a message had its second parameter marked with this attribute and made optional, the compiler would still pick the no-message one in overload resolution. Therefore, the no-message overload would have to be removed to take advantage of this feature, which would be a binary (although not source) breaking change.

Alternatives

- If being able to see source code at call sites for methods that use this attribute proves to be a problem, we can make the attribute's effects opt-in. Developers will enable it through an assembly-wide `[assembly: EnableCallerArgumentExpression]` attribute they put in `AssemblyInfo.cs`.
 - In the case the attribute's effects are not enabled, calling methods marked with the attribute would not be an error, to allow existing methods to use the attribute and maintain source compatibility. However, the attribute would be ignored and the method would be called with whatever default value was provided.

```

// Assembly1

void Foo(string bar); // V1
void Foo(string bar, string barExpression = "not provided"); // V2
void Foo(string bar, [CallerArgumentExpression("bar")] string barExpression
= "not provided"); // V3

// Assembly2

Foo(a); // V1: Compiles to Foo(a), V2, V3: Compiles to Foo(a, "not
provided")
Foo(a, "provided"); // V2, V3: Compiles to Foo(a, "provided")

// Assembly3

[assembly: EnableCallerArgumentExpression]

Foo(a); // V1: Compiles to Foo(a), V2: Compiles to Foo(a, "not provided"),
V3: Compiles to Foo(a, "a")
Foo(a, "provided"); // V2, V3: Compiles to Foo(a, "provided")

```

- To prevent the [binary compatibility problem](#) from occurring every time we want to add new caller info to `Debug.Assert`, an alternative solution would be to add a `CallerInfo` struct to the framework that contains all the necessary information about the caller.

C#

```

struct CallerInfo
{
    public string MemberName { get; set; }
    public string TypeName { get; set; }
    public string Namespace { get; set; }
    public string FullTypeName { get; set; }
    public string FilePath { get; set; }
    public int LineNumber { get; set; }
    public int ColumnNumber { get; set; }
    public Type Type { get; set; }
    public MethodBase Method { get; set; }
    public string[] ArgumentExpressions { get; set; }
}

[Flags]
enum CallerInfoOptions
{
    MemberName = 1, TypeName = 2, ...
}

public static class Debug
{
    public static void Assert(bool condition,

```

```

    // If a flag is not set here, the corresponding CallerInfo member is not populated by the caller, so it's
    // pay-for-play friendly.
    [CallerInfo(CallerInfoOptions.FilePath | CallerInfoOptions.Method |
CallerInfoOptions.ArgumentExpressions)] CallerInfo callerInfo =
default(CallerInfo)
    {
        string filePath = callerInfo.FilePath;
        MethodBase method = callerInfo.Method;
        string conditionExpression = callerInfo.ArgumentExpressions[0];
        ...
    }
}

class Bar
{
    void Foo()
    {
        Debug.Assert(false);

        // Translates to:

        var callerInfo = new CallerInfo();
        callerInfo.FilePath = @"C:\Bar.cs";
        callerInfo.Method = MethodBase.GetCurrentMethod();
        callerInfo.ArgumentExpressions = new string[] { "false" };
        Debug.Assert(false, callerInfo);
    }
}

```

This was originally proposed at <https://github.com/dotnet/csharplang/issues/87> [↗](#).

There are a few disadvantages of this approach:

- Despite being pay-for-play friendly by allowing you to specify which properties you need, it could still hurt perf significantly by allocating an array for the expressions/calling `MethodBase.GetCurrentMethod` even when the assert passes.
- Additionally, while passing a new flag to the `CallerInfo` attribute won't be a breaking change, `Debug.Assert` won't be guaranteed to actually receive that new parameter from call sites that compiled against an old version of the method.

Enhanced #line directives

Article • 2022-06-04 • 8 minutes to read

Summary

The compiler applies the mapping defined by `#line` directives to diagnostic locations and sequence points emitted to the PDB.

Currently only the line number and file path can be mapped while the starting character is inferred from the source code. The proposal is to allow specifying full span mapping.

Motivation

DSLs that generate C# source code (such as ASP.NET Razor) can't currently produce precise source mapping using `#line` directives. This results in degraded debugging experience in some cases as the sequence points emitted to the PDB can't map to the precise location in the original source code.

For example, the following Razor code

```
@page "/"
Time: @DateTime.Now
```

generates code like so (simplified):

```
C#

#line hidden
void Render()
{
    _builder.Add("Time:");
    #line 2 "page.razor"
    _builder.Add(DateTime.Now);
    #line hidden
}
```

The above directive would map the sequence point emitted by the compiler for the `_builder.Add(DateTime.Now);` statement to the line 2, but the column would be off (16 instead of 7).

The Razor source generator actually incorrectly generates the following code:

```
C#  
  
#line hidden  
void Render()  
{  
    _builder.Add("Time:");  
    _builder.Add(  
#line 2 "page.razor"  
        DateTime.Now  
#line hidden  
    );  
}
```

The intent was to preserve the starting character and it works for diagnostic location mapping. However, this does not work for sequence points since `#line` directive only applies to the sequence points that follow it. There is no sequence point in the middle of the `_builder.Add(DateTime.Now);` statement (sequence points can only be emitted at IL instructions with empty evaluation stack). The `#line 2` directive in above code thus has no effect on the generated PDB and the debugger won't place a breakpoint or stop on the `@DateTime.Now` snippet in the Razor page.

Issues addressed by this proposal: <https://github.com/dotnet/roslyn/issues/43432> <https://github.com/dotnet/roslyn/issues/46526>

Detailed design

We amend the syntax of `line_indicator` used in `pp_line` directive like so:

Current:

```
line_indicator  
    : decimal_digit+ whitespace file_name  
    | decimal_digit+  
    | 'default'  
    | 'hidden'  
    ;
```

Proposed:

```

line_indicator
  : '(' decimal_digit+ ',' decimal_digit+ ')' '-' '(' decimal_digit+ ','
decimal_digit+ ')' whitespace decimal_digit+ whitespace file_name
  | '(' decimal_digit+ ',' decimal_digit+ ')' '-' '(' decimal_digit+ ','
decimal_digit+ ')' whitespace file_name
  | decimal_digit+ whitespace file_name
  | decimal_digit+
  | 'default'
  | 'hidden'
  ;

```

That is, the `#line` directive would accept either 5 decimal numbers (*start line, start character, end line, end character, character offset*), 4 decimal numbers (*start line, start character, end line, end character*), or a single one (*line*).

If *character offset* is not specified its default value is 0, otherwise it specifies the number of UTF-16 characters. The number must be non-negative and less than length of the line following the `#line` directive in the unmapped file.

(start line, start character)-(end line, end character) specifies a span in the mapped file. *start line* and *end line* are positive integers that specify line numbers. *start character, end character* are positive integers that specify UTF-16 character numbers. *start line, start character, end line, end character* are 1-based, meaning that the first line of the file and the first UTF-16 character on each line is assigned number 1.

The implementation would constraint these numbers so that they specify a valid [sequence point source span](#) ↗:

- *start line - 1* is within range $[0, 0x20000000)$ and not equal to $0xfeeefee$.
- *end line - 1* is within range $[0, 0x20000000)$ and not equal to $0xfeeefee$.
- *start character - 1* is within range $[0, 0x10000)$
- *end character - 1* is within range $[0, 0x10000)$
- *end line* is greater or equal to *start line*.
- *start line* is equal to *end line* then *end character* is greater than *start character*.

Note that the numbers specified in the directive syntax are 1-based numbers but the actual spans in the PDB are zero-based. Hence the -1 adjustments above.

The mapped spans of sequence points and the locations of diagnostics that `#line` directive applies to are calculated as follows.

Let d be the zero-based number of the unmapped line containing the `#line` directive.

Let span $L = (\text{start: } (start\ line - 1, start\ character - 1), \text{end: } (end\ line - 1, end\ character - 1))$

be zero-based span specified by the directive.

Function M that maps a position (line, character) within the scope of the `#line` directive in the source file containing the `#line` directive to a mapped position (mapped line, mapped character) is defined as follows:

$M(l, c) =$

$$l = d + 1 \Rightarrow (L.start.line + l - d - 1, L.start.character + \max(c - character\ offset, 0))$$
$$l > d + 1 \Rightarrow (L.start.line + l - d - 1, c)$$

The syntax constructs that sequence points are associated with are determined by the compiler implementation and not covered by this specification. The compiler also decides for each sequence point its unmapped span. This span may partially or fully cover the associated syntax construct.

Once the unmapped spans are determined by the compiler the function M defined above is applied to their starting and ending positions, with the exception of the ending position of all sequence points within the scope of the `#line` directive whose unmapped location is at line $d + 1$ and character less than character offset. The end position of all these sequence points is $L.end$.

Example [5.i] demonstrates why it is necessary to provide the ability to specify the end position of the first sequence point span.

The above definition allows the generator of the unmapped source code to avoid intimate knowledge of which exact source constructs of the C# language produce sequence points. The mapped spans of the sequence points in the scope of the `#line` directive are derived from the relative position of the corresponding unmapped spans to the first unmapped span.

Specifying the *character offset* allows the generator to insert any single-line prefix on the first line. This prefix is generated code that is not present in the mapped file. Such inserted prefix affects the value of the first unmapped sequence point span. Therefore the starting character of subsequent sequence point spans need to be offset by the length of the prefix (*character offset*). See example [2].

Examples

For clarity the examples use `spanof('...')` and `lineof('...')` pseudo-syntax to express the mapped span start position and line number, respectively, of the specified code snippet.

1. First and subsequent spans

Consider the following code with unmapped zero-based line numbers listed on the right:

```
#line (1,10)-(1,15) "a" // 3  
  A();B(           // 4  
);C();           // 5  
  D();           // 6
```

$d = 3$ $L = (0, 9)..(0, 14)$

There are 4 sequence point spans the directive applies to with following unmapped and mapped spans: $(4, 2)..(4, 5) \Rightarrow (0, 9)..(0, 14)$ $(4, 6)..(5, 1) \Rightarrow (0, 15)..(1, 1)$ $(5, 2)..(5, 5) \Rightarrow (1, 2)..(1, 5)$ $(6, 4)..(6, 7) \Rightarrow (2, 4)..(2, 7)$

2. Character offset

Razor generates `_builder.Add(` prefix of length 15 (including two leading spaces).

Razor:

```
@page "/"
@F(() => 1+1,
    () => 2+2
)
```

Generated C#:

```
C#

#line hidden
void Render()
{
#line spanof('F(...)') 15 "page.razor" // 4
    _builder.Add(F(() => 1+1,           // 5
        () => 2+2                       // 6
    ));                                  // 7
#line hidden
}
};
}
```

$d = 4$ $L = (1, 1)..(3,0)$ *character offset* = 15

Spans:

- `_builder.Add(F(...)); => F(...): (5, 2)..(7, 2) => (1, 1)..(3, 0)`
- `1+1 => 1+1: (5, 23)..(5, 25) => (1, 9)..(1, 11)`
- `2+2 => 2+2: (6, 7)..(6, 9) => (2, 7)..(2, 9)`

3. Razor: Single-line span

Razor:

```
@page "/"
Time: @DateTime.Now
```

Generated C#:

```
C#
```

```

#line hidden
void Render()
{
    _builder.Add("Time:");
#line spanof('DateTime.Now') 15 "page.razor"
    _builder.Add(DateTime.Now);
#line hidden
};
}

```

4. Razor: Multi-line span

Razor:

```

@page "/"
@JsonToHtml(@"
{
    ""key1"": "value1",
    ""key2"": "value2"
}")

```

Generated C#:

```

C#

#line hidden
void Render()
{
    _builder.Add("Time:");
#line spanof('JsonToHtml(@"...")') 15 "page.razor"
    _builder.Add(JsonToHtml(@"
{
    ""key1"": "value1",
    ""key2"": "value2"
}"));
#line hidden
};
}

```

5. Razor: block constructs

i. block containing expressions

In this example, the mapped span of the first sequence point that is associated with the IL instruction that is emitted for the `_builder.Add(Html.Helper(() =>` statement needs to cover the whole expression of `Html.Helper(...)` in the generated file `a.razor`. This is achieved by application of rule [1] to the end position of the sequence point.

```
@Html.Helper(() =>
{
    <p>Hello World</p>
    @DateTime.Now
})
```

C#

```
#line spanof('Html.Helper(() => { ... })') 13 "a.razor"
_builder.Add(Html.Helper(() =>
#line lineof('{') "a.razor"
{
#line spanof('DateTime.Now') 13 "a.razor"
_builder.Add(DateTime.Now);
#line lineof('}') "a.razor"
}
#line hidden
)
```

ii. block containing statements

Uses existing `#line line file` form since

a) Razor does not add any prefix, b) `{` is not present in the generated file and there can't be a sequence point placed on it, therefore the span of the first unmapped sequence point is unknown to Razor.

The starting character of `Console` in the generated file must be aligned with the Razor file.

```
@{Console.WriteLine(1);Console.WriteLine(2);}
```

C#

```
#line lineof('@{') "a.razor"
    Console.WriteLine(1);Console.WriteLine(2);
#line hidden
```

iii. block containing top-level code (@code, @functions)

Uses existing `#line line file` form since

a) Razor does not add any prefix, b) `{` is not present in the generated file and there can't be a sequence point placed on it, therefore the span of the first unmapped sequence point is unknown to Razor.

The starting character of `[Parameter]` in the generated file must be aligned with the Razor file.

```
@code {
    [Parameter]
    public int IncrementAmount { get; set; }
}
```

C#

```
#line lineof('[') "a.razor"
    [Parameter]
    public int IncrementAmount { get; set; }
#line hidden
```

6. Razor: @for, @foreach, @while, @do, @if, @switch, @using, @try, @lock

Uses existing `#line line file` form since a) Razor does not add any prefix. b) the span of the first unmapped sequence point may not be known to Razor (or shouldn't need to know).

The starting character of the keyword in the generated file must be aligned with the Razor file.

```
@for (var i = 0; i < 10; i++)
{
}
@if (condition)
{
}
else
```

```
{  
}
```

C#

```
#line lineof('for') "a.razor"  
for (var i = 0; i < 10; i++)  
{  
}  
#line lineof('if') "a.razor"  
if (condition)  
{  
}  
else  
{  
}  
#line hidden
```

Improved Definite Assignment Analysis

Article • 2022-05-29 • 13 minutes to read

Summary

Definite assignment §9.4 as specified has a few gaps which have caused users inconvenience. In particular, scenarios involving comparison to boolean constants, conditional-access, and null coalescing.

Related discussions and issues

csharp-lang discussion of this proposal:

<https://github.com/dotnet/csharp-lang/discussions/4240>

Probably a dozen or so user reports can be found via this or similar queries (i.e. search for "definite assignment" instead of "CS0165", or search in csharp-lang).

[https://github.com/dotnet/roslyn/issues?](https://github.com/dotnet/roslyn/issues?q=is%3Aclosed+is%3Aissue+label%3A%22Resolution-By+Design%22+cs0165)

[q=is%3Aclosed+is%3Aissue+label%3A%22Resolution-By+Design%22+cs0165](https://github.com/dotnet/roslyn/issues?q=is%3Aclosed+is%3Aissue+label%3A%22Resolution-By+Design%22+cs0165)

I have included related issues in the scenarios below to give a sense of the relative impact of each scenario.

Scenarios

As a point of reference, let's start with a well-known "happy case" that does work in definite assignment and in nullable.

```
C#
```

```
#nullable enable
```

```
C c = new C();  
if (c != null && c.M(out object obj0))  
{  
    obj0.ToString(); // ok  
}
```

```
public class C  
{  
    public bool M(out object obj)  
    {  
        obj = new object();  
        return true;  
    }  
}
```

```
}  
}
```

Comparison to bool constant

- <https://github.com/dotnet/csharplang/discussions/801> ↗
- <https://github.com/dotnet/roslyn/issues/45582> ↗
 - Links to 4 other issues where people were affected by this.

C#

```
if ((c != null && c.M(out object obj1)) == true)  
{  
    obj1.ToString(); // undesired error  
}  
  
if ((c != null && c.M(out object obj2)) is true)  
{  
    obj2.ToString(); // undesired error  
}
```

Comparison between a conditional access and a constant value

- <https://github.com/dotnet/roslyn/issues/33559> ↗
- <https://github.com/dotnet/csharplang/discussions/4214> ↗
- <https://github.com/dotnet/csharplang/issues/3659> ↗
- <https://github.com/dotnet/csharplang/issues/3485> ↗
- <https://github.com/dotnet/csharplang/issues/3659> ↗

This scenario is probably the biggest one. We do support this in nullable but not in definite assignment.

C#

```
if (c?.M(out object obj3) == true)  
{  
    obj3.ToString(); // undesired error  
}
```

Conditional access coalesced to a bool constant

- <https://github.com/dotnet/csharplang/discussions/916> ↗

- <https://github.com/dotnet/csharplang/issues/3365> ↗

This scenario is very similar to the previous one. This is also supported in nullable but not in definite assignment.

```
C#  
  
if (c?.M(out object obj4) ?? false)  
{  
    obj4.ToString(); // undesired error  
}
```

Conditional expressions where one arm is a bool constant

- <https://github.com/dotnet/roslyn/issues/4272> ↗

It's worth pointing out that we already have special behavior for when the condition expression is constant (i.e. `true ? a : b`). We just unconditionally visit the arm indicated by the constant condition and ignore the other arm.

Also note that we haven't handled this scenario in nullable.

```
C#  
  
if (c != null ? c.M(out object obj4) : false)  
{  
    obj4.ToString(); // undesired error  
}
```

Specification

?. (null-conditional operator) expressions

We introduce a new section **?. (null-conditional operator) expressions**. See the null-conditional operator specification ([§11.7.7](#) ↗) and Precise rules for determining definite assignment [§9.4.4](#) ↗ for context.

As in the definite assignment rules linked above, we refer to a given initially unassigned variable as v .

We introduce the concept of "directly contains". An expression E is said to "directly contain" a subexpression E_1 if it is not subject to a user-defined conversion [§10.5](#) ↗

whose parameter is not of a non-nullable value type, and one of the following conditions holds:

- E is E_1 . For example, `a?.b()` directly contains the expression `a?.b()`.
- If E is a parenthesized expression `(E2)`, and E_2 directly contains E_1 .
- If E is a null-forgiving operator expression `E2!`, and E_2 directly contains E_1 .
- If E is a cast expression `(T)E2`, and the cast does not subject E_2 to a non-lifted user-defined conversion whose parameter is not of a non-nullable value type, and E_2 directly contains E_1 .

For an expression E of the form `primary_expression null_conditional_operations`, let E_0 be the expression obtained by textually removing the leading `?` from each of the `null_conditional_operations` of E that have one, as in the linked specification above.

In subsequent sections we will refer to E_0 as the *non-conditional counterpart* to the null-conditional expression. Note that some expressions in subsequent sections are subject to additional rules that only apply when one of the operands directly contains a null-conditional expression.

- The definite assignment state of v at any point within E is the same as the definite assignment state at the corresponding point within E_0 .
- The definite assignment state of v after E is the same as the definite assignment state of v after *primary_expression*.

Remarks

We use the concept of "directly contains" to allow us to skip over relatively simple "wrapper" expressions when analyzing conditional accesses that are compared to other values. For example, `((a?.b(out x))!) == true` is expected to result in the same flow state as `a?.b == true` in general.

We also want to allow analysis to function in the presence of a number of possible conversions on a conditional access. Propagating out "state when not null" is not possible when the conversion is user-defined, though, since we can't count on user-defined conversions to honor the constraint that the output is non-null only if the input is non-null. The only exception to this is when the user-defined conversion's input is a non-nullable value type. For example:

```
C#
```

```
public struct S1 { }  
public struct S2 { public static implicit operator S2?(S1 s1) => null; }
```

This also includes lifted conversions like the following:

```
C#  
  
string x;  
  
S1? s1 = null;  
_ = s1?.M1(x = "a") ?? s1.Value.M2(x = "a");  
  
x.ToString(); // ok  
  
public struct S1  
{  
    public S1 M1(object obj) => this;  
    public S2 M2(object obj) => new S2();  
}  
public struct S2  
{  
    public static implicit operator S2(S1 s1) => null;  
}
```

When we consider whether a variable is assigned at a given point within a null-conditional expression, we simply assume that any preceding null-conditional operations within the same null-conditional expression succeeded.

For example, given a conditional expression `a?.b(out x)?.c(x)`, the non-conditional counterpart is `a.b(out x).c(x)`. If we want to know the definite assignment state of `x` before `?.c(x)`, for example, then we perform a "hypothetical" analysis of `a.b(out x)` and use the resulting state as an input to `?.c(x)`.

Boolean constant expressions

We introduce a new section "Boolean constant expressions":

For an expression `expr` where `expr` is a constant expression with a bool value:

- The definite assignment state of `v` after `expr` is determined by:
 - If `expr` is a constant expression with value `true`, and the state of `v` before `expr` is "not definitely assigned", then the state of `v` after `expr` is "definitely assigned when false".
 - If `expr` is a constant expression with value `false`, and the state of `v` before `expr` is "not definitely assigned", then the state of `v` after `expr` is "definitely assigned when true".

Remarks

We assume that if an expression has a constant value `bool false`, for example, it's impossible to reach any branch that requires the expression to return `true`. Therefore variables are assumed to be definitely assigned in such branches. This ends up combining nicely with the spec changes for expressions like `??` and `?:` and enabling a lot of useful scenarios.

It's also worth noting that we never expect to be in a conditional state *before* visiting a constant expression. That's why we do not account for scenarios such as "*expr* is a constant expression with value *true*, and the state of *v* before *expr* is "definitely assigned when true".

?? (null-coalescing expressions) augment

We augment section [§9.4.4.29](#) as follows:

For an expression *expr* of the form `expr_first ?? expr_second`:

- ...
- The definite assignment state of *v* after *expr* is determined by:
 - ...
 - If *expr_first* directly contains a null-conditional expression *E*, and *v* is definitely assigned after the non-conditional counterpart *E₀*, then the definite assignment state of *v* after *expr* is the same as the definite assignment state of *v* after *expr_second*.

Remarks

The above rule formalizes that for an expression like `a?.M(out x) ?? (x = false)`, either the `a?.M(out x)` was fully evaluated and produced a non-null value, in which case `x` was assigned, or the `x = false` was evaluated, in which case `x` was also assigned. Therefore `x` is always assigned after this expression.

This also handles the `dict?.TryGetValue(key, out var value) ?? false` scenario, by observing that *v* is definitely assigned after `dict.TryGetValue(key, out var value)`, and *v* is "definitely assigned when true" after `false`, and concluding that *v* must be "definitely assigned when true".

The more general formulation also allows us to handle some more unusual scenarios, such as:

- `if (x?.M(out y) ?? (b && z.M(out y))) y.ToString();`
- `if (x?.M(out y) ?? z?.M(out y) ?? false) y.ToString();`

?: (conditional) expressions

We augment section [§9.4.4.30](#) as follows:

For an expression *expr* of the form `expr_cond ? expr_true : expr_false`:

- ...
- The definite assignment state of *v* after *expr* is determined by:
 - ...
 - If the state of *v* after *expr_true* is "definitely assigned when true", and the state of *v* after *expr_false* is "definitely assigned when true", then the state of *v* after *expr* is "definitely assigned when true".
 - If the state of *v* after *expr_true* is "definitely assigned when false", and the state of *v* after *expr_false* is "definitely assigned when false", then the state of *v* after *expr* is "definitely assigned when false".

Remarks

This makes it so when both arms of a conditional expression result in a conditional state, we join the corresponding conditional states and propagate it out instead of unsplitting the state and allowing the final state to be non-conditional. This enables scenarios like the following:

```
C#  
  
bool b = true;  
object x = null;  
int y;  
if (b ? x != null && Set(out y) : x != null && Set(out y))  
{  
    y.ToString();  
}  
  
bool Set(out int x) { x = 0; return true; }
```

This is an admittedly niche scenario, that compiles without error in the native compiler, but was broken in Roslyn in order to match the specification at the time. See [internal issue](#).

==/!= (relational equality operator) expressions

We introduce a new section `==/!= (relational equality operator) expressions`.

The general rules for expressions with embedded expressions [§9.4.4.23](#) apply, except for the scenarios described below.

For an expression *expr* of the form `expr_first == expr_second`, where `==` is a predefined comparison operator ([§11.11](#)) or a lifted operator ([§11.4.8](#)), the definite assignment state of *v* after *expr* is determined by:

- If *expr_first* directly contains a null-conditional expression *E* and *expr_second* is a constant expression with value *null*, and the state of *v* after the non-conditional counterpart *E*₀ is "definitely assigned", then the state of *v* after *expr* is "definitely assigned when false".
- If *expr_first* directly contains a null-conditional expression *E* and *expr_second* is an expression of a non-nullable value type, or a constant expression with a non-null value, and the state of *v* after the non-conditional counterpart *E*₀ is "definitely assigned", then the state of *v* after *expr* is "definitely assigned when true".
- If *expr_first* is of type *boolean*, and *expr_second* is a constant expression with value *true*, then the definite assignment state after *expr* is the same as the definite assignment state after *expr_first*.
- If *expr_first* is of type *boolean*, and *expr_second* is a constant expression with value *false*, then the definite assignment state after *expr* is the same as the definite assignment state of *v* after the logical negation expression `!expr_first`.

For an expression *expr* of the form `expr_first != expr_second`, where `!=` is a predefined comparison operator ([§11.11](#)) or a lifted operator ([§11.4.8](#)), the definite assignment state of *v* after *expr* is determined by:

- If *expr_first* directly contains a null-conditional expression *E* and *expr_second* is a constant expression with value *null*, and the state of *v* after the non-conditional counterpart *E*₀ is "definitely assigned", then the state of *v* after *expr* is "definitely assigned when true".
- If *expr_first* directly contains a null-conditional expression *E* and *expr_second* is an expression of a non-nullable value type, or a constant expression with a non-null value, and the state of *v* after the non-conditional counterpart *E*₀ is "definitely assigned", then the state of *v* after *expr* is "definitely assigned when false".
- If *expr_first* is of type *boolean*, and *expr_second* is a constant expression with value *true*, then the definite assignment state after *expr* is the same as the definite assignment state of *v* after the logical negation expression `!expr_first`.
- If *expr_first* is of type *boolean*, and *expr_second* is a constant expression with value *false*, then the definite assignment state after *expr* is the same as the definite assignment state after *expr_first*.

All of the above rules in this section are commutative, meaning that if a rule applies when evaluated in the form `expr_second op expr_first`, it also applies in the form `expr_first op expr_second`.

Remarks

The general idea expressed by these rules is:

- if a conditional access is compared to `null`, then we know the operations definitely occurred if the result of the comparison is `false`
- if a conditional access is compared to a non-nullable value type or a non-null constant, then we know the operations definitely occurred if the result of the comparison is `true`.
- since we can't trust user-defined operators to provide reliable answers where initialization safety is concerned, the new rules only apply when a predefined `==/!=` operator is in use.

We may eventually want to refine these rules to thread through conditional state which is present at the end of a member access or call. Such scenarios don't really happen in definite assignment, but they do happen in nullable in the presence of `[NotNullWhen(true)]` and similar attributes. This would require special handling for `bool` constants in addition to just handling for `null`/non-null constants.

Some consequences of these rules:

- `if (a?.b(out var x) == true) x() else x();` will error in the 'else' branch
- `if (a?.b(out var x) == 42) x() else x();` will error in the 'else' branch
- `if (a?.b(out var x) == false) x() else x();` will error in the 'else' branch
- `if (a?.b(out var x) == null) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != true) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != 42) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != false) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != null) x() else x();` will error in the 'else' branch

is operator and is pattern expressions

We introduce a new section `is operator and is pattern expressions`.

For an expression `expr` of the form `E is T`, where `T` is any type or pattern

- The definite assignment state of v before E is the same as the definite assignment state of v before $expr$.
- The definite assignment state of v after $expr$ is determined by:
 - If E directly contains a null-conditional expression, and the state of v after the non-conditional counterpart E_0 is "definitely assigned", and T is any type or a pattern that does not match a `null` input, then the state of v after $expr$ is "definitely assigned when true".
 - If E directly contains a null-conditional expression, and the state of v after the non-conditional counterpart E_0 is "definitely assigned", and T is a pattern that matches a `null` input, then the state of v after $expr$ is "definitely assigned when false".
 - If E is of type `boolean` and T is a pattern which only matches a `true` input, then the definite assignment state of v after $expr$ is the same as the definite assignment state of v after E .
 - If E is of type `boolean` and T is a pattern which only matches a `false` input, then the definite assignment state of v after $expr$ is the same as the definite assignment state of v after the logical negation expression `!expr`.
 - Otherwise, if the definite assignment state of v after E is "definitely assigned", then the definite assignment state of v after $expr$ is "definitely assigned".

Remarks

This section is meant to address similar scenarios as in the `==/!=` section above. This specification does not address recursive patterns, e.g. `(a?.b(out x), c?.d(out y)) is (object, object)`. Such support may come later if time permits.

Additional scenarios

This specification doesn't currently address scenarios involving pattern switch expressions and switch statements. For example:

```
C#
_ = c?.M(out object obj4) switch
{
    not null => obj4.ToString() // undesired error
};
```

It seems like support for this could come later if time permits.

There have been several categories of bugs filed for nullable which require we essentially increase the sophistication of pattern analysis. It is likely that any ruling we make which improves definite assignment would also be carried over to nullable.

<https://github.com/dotnet/roslyn/issues/49353> ↗

<https://github.com/dotnet/roslyn/issues/46819> ↗

<https://github.com/dotnet/roslyn/issues/44127> ↗

Drawbacks

It feels odd to have the analysis "reach down" and have special recognition of conditional accesses, when typically flow analysis state is supposed to propagate upward. We are concerned about how a solution like this could intersect painfully with possible future language features that do null checks.

Alternatives

Two alternatives to this proposal:

1. Introduce "state when null" and "state when not null" to the language and compiler. This has been judged to be too much effort for the scenarios we are trying to solve, but that we could potentially implement the above proposal and then move to a "state when null/not null" model later on without breaking people.
2. Do nothing.

Unresolved questions

There are impacts on switch expressions that should be specified:

AsyncMethodBuilder override

Article • 2021-09-21 • 8 minutes to read

Summary

Allow per-method override of the async method builder to use. For some async methods we want to customize the invocation of `Builder.Create()` to use a different *builder type*.

C#

```
[AsyncMethodBuilderAttribute(typeof(PoolingAsyncValueTaskMethodBuilder<>))]
// new usage of AsyncMethodBuilderAttribute type
static async ValueTask<int> ExampleAsync() { ... }
```

Motivation

Today, async method builders are tied to a given type used as a return type of an async method. For example, any method that's declared as `async Task` uses `AsyncTaskMethodBuilder`, and any method that's declared as `async ValueTask<T>` uses `AsyncValueTaskMethodBuilder<T>`. This is due to the `[AsyncMethodBuilder(Type)]` attribute on the type used as a return type, e.g. `ValueTask<T>` is attributed as `[AsyncMethodBuilder(typeof(AsyncValueTaskMethodBuilder<>))]`. This addresses the majority common case, but it leaves a few notable holes for advanced scenarios.

In .NET 5, an experimental feature was shipped that provides two modes in which `AsyncValueTaskMethodBuilder` and `AsyncValueTaskMethodBuilder<T>` operate. The on-by-default mode is the same as has been there since the functionality was introduced: when the state machine needs to be lifted to the heap, an object is allocated to store the state, and the async method returns a `ValueTask{<T>}` backed by a `Task{<T>}`. However, if an environment variable is set, all builders in the process switch to a mode where, instead, the `ValueTask{<T>}` instances are backed by reusable `IValueTaskSource{<T>}` implementations that are pooled. Each async method has its own pool with a fixed maximum number of instances allowed to be pooled, and as long as no more than that number are ever returned to the pool to be pooled at the same time, `async ValueTask{<T>}` methods effectively become free of any GC allocation overhead.

There are several problems with this experimental mode, however, which is both why a) it's off by default and b) we're likely to remove it in a future release unless very

compelling new information emerges

(<https://github.com/dotnet/runtime/issues/13633>).

- It introduces a behavioral difference for consumers of the returned `ValueTask{<T>}` if that `ValueTask` isn't being consumed according to spec. When it's backed by a `Task`, you can do with the `ValueTask` things you can do with a `Task`, like await it multiple times, await it concurrently, block waiting for it to complete, etc. But when it's backed by an arbitrary `IValueTaskSource`, such operations are prohibited, and automatically switching from the former to the latter can lead to bugs. With the switch at the process level and affecting all `async ValueTask` methods in the process, whether you control them or not, it's too big a hammer.
- It's not necessarily a performance win, and could represent a regression in some situations. The implementation is trading the cost of pooling (accessing a pool isn't free) with the cost of GC, and in various situations the GC can win. Again, applying the pooling to all `async ValueTask` methods in the process rather than being selective about the ones it would most benefit is too big a hammer.
- It adds to the IL size of a trimmed application, even if the flag isn't set, and then to the resulting asm size. It's possible that can be worked around with improvements to the implementation to teach it that for a given deployment the environment variable will always be false, but as it stands today, every `async ValueTask` method saw for example an ~2K binary footprint increase in aot images due to this option, and, again, that applies to all `async ValueTask` methods in the whole application closure.
- Different methods may benefit from differing levels of control, e.g. the size of the pool employed because of knowledge of the method and how it's used, but the same setting is applied to all uses of the builder. One could imagine working around that by having the builder code use reflection at runtime to look for some attribute, but that adds significant run-time expense, and likely on the startup path.

On top of all of these issues with the existing pooling, it's also the case that developers are prevented from writing their own customized builders for types they don't own. If, for example, a developer wants to implement their own pooling support, they also have to introduce a brand new task-like type, rather than just being able to use `{Value}Task{<T>}`, because the attribute specifying the builder is only specifiable on the type declaration of the return type.

We need a way to have an individual async method opt-in to a specific builder.

Detailed design

Using AsyncMethodBuilderAttribute on methods

In `dotnet/runtime`, add `AttributeTargets.Method` to the targets for

`System.Runtime.CompilerServices.AsyncMethodBuilderAttribute`:

```
C#

namespace System.Runtime.CompilerServices
{
    /// <summary>
    /// Indicates the type of the async method builder that should be used
    /// by a language compiler:
    /// - to build the return type of an async method that is attributed,
    /// - to build the attributed type when used as the return type of an
    /// async method.
    /// </summary>
    [AttributeUsage(AttributeTargets.Method | AttributeTargets.Class |
AttributeTargets.Struct | AttributeTargets.Interface |
AttributeTargets.Delegate | AttributeTargets.Enum, Inherited = false,
AllowMultiple = false)]
    public sealed class AsyncMethodBuilderAttribute : Attribute
    {
        /// <summary>Initializes the <see
        cref="AsyncMethodBuilderAttribute"/>.</summary>
        /// <param name="builderType">The <see cref="Type"/> of the
        associated builder.</param>
        public AsyncMethodBuilderAttribute(Type builderType) => BuilderType
        = builderType;

        /// <summary>Gets the <see cref="Type"/> of the associated builder.
        </summary>
        public Type BuilderType { get; }
    }
}
```

This allows the attribute to be applied on methods or local functions or lambdas.

Example of usage on a method:

```
C#

[AsyncMethodBuilder(typeof(PoolingAsyncValueTaskMethodBuilder<>))] // new
usage, referring to some custom builder type
static async ValueTask<int> ExampleAsync() { ... }
```

It is an error to apply the attribute multiple times on a given method.

It is an error to apply the attribute to a lambda with an implicit return type.

A developer who wants to use a specific custom builder for all of their methods can do so by putting the relevant attribute on each method.

Determining the builder type for an async method

When compiling an async method, the builder type is determined by:

1. using the builder type from the `AsyncMethodBuilder` attribute if one is present,
2. otherwise, falling back to the builder type determined by previous approach. (see [spec for task-like types](#) ↗).

If an `AsyncMethodBuilder` attribute is present, we take the builder type specified by the attribute and construct it if necessary.

If the override type is an open generic type, take the single type argument of the async method's return type and substitute it into the override type.

If the override type is a bound generic type, then we produce an error.

If the async method's return type does not have a single type argument, then we produce an error.

We verify that the builder type is compatible with the return type of the async method:

1. look for the public `Create` method with no type parameters and no parameters on the constructed builder type.
It is an error if the method is not found. It is an error if the method returns a type other than the constructed builder type.
2. look for the public `Task` property.
It is an error if the property is not found.
3. consider the type of that `Task` property (a task-like type):
It is an error if the task-like type does not matches the return type of the async method.

Note that it is not necessary for the return type of the method to be a task-like type.

Execution

The builder type determined above is used as part of the existing async method design.

For example, today if a method is defined as:

```
C#  
  
public async ValueTask<T> ExampleAsync() { ... }
```

the compiler will generate code akin to:

```
C#  
  
[AsyncStateMachine(typeof(<ExampleAsync>d__29))]  
[CompilerGenerated]  
static ValueTask<int> ExampleAsync()  
{  
    <ExampleAsync>d__29 stateMachine;  
    stateMachine.<>t__builder = AsyncValueTaskMethodBuilder<int>.Create();  
    stateMachine.<>1__state = -1;  
    stateMachine.<>t__builder.Start(ref stateMachine);  
    return stateMachine.<>t__builder.Task;  
}
```

With this change, if the developer wrote:

```
C#  
  
[AsyncMethodBuilder(typeof(PoolingAsyncValueTaskMethodBuilder<>))] // new  
usage, referring to some custom builder type  
static async ValueTask<int> ExampleAsync() { ... }
```

it would instead be compiled to:

```
C#  
  
[AsyncStateMachine(typeof(<ExampleAsync>d__29))]  
[CompilerGenerated]  
[AsyncMethodBuilder(typeof(PoolingAsyncValueTaskMethodBuilder<>))] //  
retained but not necessary anymore  
static ValueTask<int> ExampleAsync()  
{  
    <ExampleAsync>d__29 stateMachine;  
    stateMachine.<>t__builder =  
    PoolingAsyncValueTaskMethodBuilder<int>.Create(); // <>t__builder now a  
    different type  
    stateMachine.<>1__state = -1;  
    stateMachine.<>t__builder.Start(ref stateMachine);  
    return stateMachine.<>t__builder.Task;  
}
```

Just those small additions enable:

- Anyone to write their own builder that can be applied to async methods that return `Task<T>` and `ValueTask<T>`
- As "anyone", the runtime to ship the experimental builder support as new public builder types that can be opted into on a method-by-method basis; the existing

support would be removed from the existing builders. Methods (including some we care about in the core libraries) can then be attributed on a case-by-case basis to use the pooling support, without impacting any other unattributed methods.

and with minimal surface area changes or feature work in the compiler.

Note that we need the emitted code to allow a different type being returned from

`Create` method:

```
AsyncPooledBuilder _builder = AsyncPooledBuilderWithSize4.Create();
```

Note that this mechanism to change the the builder type cannot be used when the synthesized entry-point for top-level statements is async. An explicit entry-point should be used instead.

Drawbacks

- The syntax for applying such an attribute to a method is verbose. The impact of this is lessened if a developer can apply it to multiple methods en mass, e.g. at the type or module level.

Alternatives

- Implement a different task-like type and expose that difference to consumers. `ValueTask` was made extensible via the `IValueTaskSource` interface to avoid that need, however.
- Address just the `ValueTask` pooling part of the issue by enabling the experiment as the on-by-default-and-only implementation. That doesn't address other aspects, such as configuring the pooling, or enabling someone else to provide their own builder.
- Earlier versions of this document allowed for scoped override of builder types.

Unresolved questions

1. **Replace or also create.** All of the examples in this proposal are about replacing a buildable task-like's builder. Should the feature be scoped to just that? Or should you be able to use this attribute on a method with a return type that doesn't already have a builder (e.g. some common interface)? That could impact overload resolution.

2. **Private Builders.** Should the compiler support non-public async method builders? This is not spec'd today, but experimentally we only support public ones. That makes some sense when the attribute is applied to a type to control what builder is used with that type, since anyone writing an async method with that type as the return type would need access to the builder. However, with this new feature, when that attribute is applied to a method, it only impacts the implementation of that method, and thus could reasonably reference a non-public builder. Likely we will want to support library authors who have non-public ones they want to use.

Static abstract members in interfaces

Article • 2022-09-29 • 15 minutes to read

- [x] Proposed
- [] Prototype: Not Started
- [] Implementation: Not Started
- [] Specification: Not Started

Summary

An interface is allowed to specify abstract static members that implementing classes and structs are then required to provide an explicit or implicit implementation of. The members can be accessed off of type parameters that are constrained by the interface.

Motivation

There is currently no way to abstract over static members and write generalized code that applies across types that define those static members. This is particularly problematic for member kinds that *only* exist in a static form, notably operators.

This feature allows generic algorithms over numeric types, represented by interface constraints that specify the presence of given operators. The algorithms can therefore be expressed in terms of such operators:

c#

```
// Interface specifies static properties and operators
interface IAddable<T> where T : IAddable<T>
{
    static abstract T Zero { get; }
    static abstract T operator +(T t1, T t2);
}

// Classes and structs (including built-ins) can implement interface
struct Int32 : ..., IAddable<Int32>
{
    static Int32 I.operator +(Int32 x, Int32 y) => x + y; // Explicit
    public static int Zero => 0; // Implicit
}

// Generic algorithms can use static members on T
public static T AddAll<T>(T[] ts) where T : IAddable<T>
{
    T result = T.Zero; // Call static operator
    foreach (T t in ts) { result += t; } // Use `+`
}
```

```
    return result;
}

// Generic method can be applied to built-in and user-defined types
int sixtyThree = AddAll(new [] { 1, 2, 4, 8, 16, 32 });
```

Syntax

Interface members

The feature would allow static interface members to be declared virtual.

Today's rules

Today, instance members in interfaces are implicitly abstract (or virtual if they have a default implementation), but can optionally have an `abstract` (or `virtual`) modifier. Non-virtual instance members must be explicitly marked as `sealed`.

Static interface members today are implicitly non-virtual, and do not allow `abstract`, `virtual` or `sealed` modifiers.

Proposal

Abstract static members

Static interface members other than fields are allowed to also have the `abstract` modifier. Abstract static members are not allowed to have a body (or in the case of properties, the accessors are not allowed to have a body).

```
c#

interface I<T> where T : I<T>
{
    static abstract void M();
    static abstract T P { get; set; }
    static abstract event Action E;
    static abstract T operator +(T l, T r);
    static abstract bool operator ==(T l, T r);
    static abstract bool operator !=(T l, T r);
    static abstract implicit operator T(string s);
    static abstract explicit operator string(T t);
}
```

Virtual static members

Static interface members other than fields are allowed to also have the `virtual` modifier. Virtual static members are required to have a body.

c#

```
interface I<T> where T : I<T>
{
    static virtual void M() {}
    static virtual T P { get; set; }
    static virtual event Action E;
    static virtual T operator +(T l, T r) { throw new
    NotImplementedException(); }
}
```

Explicitly non-virtual static members

For symmetry with non-virtual instance members, static members should be allowed an optional `sealed` modifier, even though they are non-virtual by default:

c#

```
interface I0
{
    static sealed void M() => Console.WriteLine("Default behavior");

    static sealed int f = 0;

    static sealed int P1 { get; set; }
    static sealed int P2 { get => f; set => f = value; }

    static sealed event Action E1;
    static sealed event Action E2 { add => E1 += value; remove => E1 -=
    value; }

    static sealed I0 operator +(I0 l, I0 r) => l;
}
```

Implementation of interface members

Today's rules

Classes and structs can implement abstract instance members of interfaces either implicitly or explicitly. An implicitly implemented interface member is a normal (virtual or non-virtual) member declaration of the class or struct that just "happens" to also

implement the interface member. The member can even be inherited from a base class and thus not even be present in the class declaration.

An explicitly implemented interface member uses a qualified name to identify the interface member in question. The implementation is not directly accessible as a member on the class or struct, but only through the interface.

Proposal

No new syntax is needed in classes and structs to facilitate implicit implementation of static abstract interface members. Existing static member declarations serve that purpose.

Explicit implementations of static abstract interface members use a qualified name along with the `static` modifier.

c#

```
class C : I<C>
{
    string _s;
    public C(string s) => _s = s;
    static void I<C>.M() => Console.WriteLine("Implementation");
    static C I<C>.P { get; set; }
    static event Action I<C>.E;
    static C I<C>.operator +(C l, C r) => new C($"{l._s} {r._s}");
    static bool I<C>.operator ==(C l, C r) => l._s == r._s;
    static bool I<C>.operator !=(C l, C r) => l._s != r._s;
    static implicit I<C>.operator C(string s) => new C(s);
    static explicit I<C>.operator string(C c) => c._s;
}
```

Semantics

Operator restrictions

Today all unary and binary operator declarations have some requirement involving at least one of their operands to be of type `T` or `T?`, where `T` is the instance type of the enclosing type.

These requirements need to be relaxed so that a restricted operand is allowed to be of a type parameter that counts as "the instance type of the enclosing type".

In order for a type parameter `T` to count as "the instance type of the enclosing type", it must meet the following requirements:

- `T` is a direct type parameter on the interface in which the operator declaration occurs, and
- `T` is *directly* constrained by what the spec calls the "instance type" - i.e. the surrounding interface with its own type parameters used as type arguments.

Equality operators and conversions

Abstract/virtual declarations of `==` and `!=` operators, as well as abstract/virtual declarations of implicit and explicit conversion operators will be allowed in interfaces. Derived interfaces will be allowed to implement them too.

For `==` and `!=` operators, at least one parameter type must be a type parameter that counts as "the instance type of the enclosing type", as defined in the previous section.

Implementing static abstract members

The rules for when a static member declaration in a class or struct is considered to implement a static abstract interface member, and for what requirements apply when it does, are the same as for instance members.

TBD: There may be additional or different rules necessary here that we haven't yet thought of.

Interfaces as type arguments

We discussed the issue raised by <https://github.com/dotnet/csharpplang/issues/5955> and decided to add a restriction around usage of an interface as a type argument (<https://github.com/dotnet/csharpplang/blob/main/meetings/2022/LDM-2022-03-28.md#type-hole-in-static-abstracts>). Here is the restriction as it was proposed by <https://github.com/dotnet/csharpplang/issues/5955> and approved by the LDM.

An interface containing or inheriting a static abstract/virtual member that does not have most specific implementation in the interface cannot be used as a type argument. If all static abstract/virtual members have most specific implementation, the interface can be used as a type argument.

Accessing static abstract interface members

A static abstract interface member `M` may be accessed on a type parameter `T` using the expression `T.M` when `T` is constrained by an interface `I` and `M` is an accessible static abstract member of `I`.

```
c#  
  
T M<T>() where T : I<T>  
{  
    T.M();  
    T t = T.P;  
    T.E += () => { };  
    return t + T.P;  
}
```

At runtime, the actual member implementation used is the one that exists on the actual type provided as a type argument.

```
c#  
  
C c = M<C>(); // The static members of C get called
```

Since query expressions are spec'ed as a syntactic rewrite, C# actually lets you use a *type* as the query source, as long as it has static members for the query operators you use! In other words, if the *syntax* fits, we allow it! We think this behavior was not intentional or important in the original LINQ, and we don't want to do the work to support it on type parameters. If there are scenarios out there we will hear about them, and can choose to embrace this later.

Variance safety [§17.2.3.2](#)

Variance safety rules should apply to signatures of static abstract members. The addition proposed in <https://github.com/dotnet/csharplang/blob/main/proposals/variance-safety-for-static-interface-members.md#variance-safety> should be adjusted from

These restrictions do not apply to occurrences of types within declarations of static members.

to

*These restrictions do not apply to occurrences of types within declarations of **non-virtual, non-abstract** static members.*

[§10.5.4](#) User defined implicit conversions

The following bullet points

- Determine the types S , S_0 and T_0 .
 - If E has a type, let S be that type.
 - If S or T are nullable value types, let S_i and T_i be their underlying types, otherwise let S_i and T_i be S and T , respectively.
 - If S_i or T_i are type parameters, let S_0 and T_0 be their effective base classes, otherwise let S_0 and T_0 be S_x and T_i , respectively.
- Find the set of types, D , from which user-defined conversion operators will be considered. This set consists of S_0 (if S_0 is a class or struct), the base classes of S_0 (if S_0 is a class), and T_0 (if T_0 is a class or struct).
- Find the set of applicable user-defined and lifted conversion operators, U . This set consists of the user-defined and lifted implicit conversion operators declared by the classes or structs in D that convert from a type encompassing S to a type encompassed by T . If U is empty, the conversion is undefined and a compile-time error occurs.

are adjusted as follows:

- Determine the types S , S_0 and T_0 .
 - If E has a type, let S be that type.
 - If S or T are nullable value types, let S_i and T_i be their underlying types, otherwise let S_i and T_i be S and T , respectively.
 - If S_i or T_i are type parameters, let S_0 and T_0 be their effective base classes, otherwise let S_0 and T_0 be S_x and T_i , respectively.
- Find the set of applicable user-defined and lifted conversion operators, U .
 - Find the set of types, D_1 , from which user-defined conversion operators will be considered. This set consists of S_0 (if S_0 is a class or struct), the base classes of S_0 (if S_0 is a class), and T_0 (if T_0 is a class or struct).
 - Find the set of applicable user-defined and lifted conversion operators, U_1 . This set consists of the user-defined and lifted implicit conversion operators declared by the classes or structs in D_1 that convert from a type encompassing S to a type encompassed by T .
 - If U_1 is not empty, then U is U_1 . Otherwise,
 - Find the set of types, D_2 , from which user-defined conversion operators will be considered. This set consists of S_i *effective interface set* and their base interfaces (if S_i is a type parameter), and T_i *effective interface set* (if T_i is a type parameter).

- Find the set of applicable user-defined and lifted conversion operators, U_2 . This set consists of the user-defined and lifted implicit conversion operators declared by the interfaces in D_2 that convert from a type encompassing S to a type encompassed by T .
- If U_2 is not empty, then U is U_2
- If U is empty, the conversion is undefined and a compile-time error occurs.

§10.5.5 [↗](#) User-defined explicit conversions

The following bullet points

- Determine the types S , S_0 and T_0 .
 - If E has a type, let S be that type.
 - If S or T are nullable value types, let S_i and T_i be their underlying types, otherwise let S_i and T_i be S and T , respectively.
 - If S_i or T_i are type parameters, let S_0 and T_0 be their effective base classes, otherwise let S_0 and T_0 be S_i and T_i , respectively.
- Find the set of types, D , from which user-defined conversion operators will be considered. This set consists of S_0 (if S_0 is a class or struct), the base classes of S_0 (if S_0 is a class), T_0 (if T_0 is a class or struct), and the base classes of T_0 (if T_0 is a class).
- Find the set of applicable user-defined and lifted conversion operators, U . This set consists of the user-defined and lifted implicit or explicit conversion operators declared by the classes or structs in D that convert from a type encompassing or encompassed by S to a type encompassing or encompassed by T . If U is empty, the conversion is undefined and a compile-time error occurs.

are adjusted as follows:

- Determine the types S , S_0 and T_0 .
 - If E has a type, let S be that type.
 - If S or T are nullable value types, let S_i and T_i be their underlying types, otherwise let S_i and T_i be S and T , respectively.
 - If S_i or T_i are type parameters, let S_0 and T_0 be their effective base classes, otherwise let S_0 and T_0 be S_i and T_i , respectively.
- Find the set of applicable user-defined and lifted conversion operators, U .
 - Find the set of types, D_1 , from which user-defined conversion operators will be considered. This set consists of S_0 (if S_0 is a class or struct), the base classes of

<https://github.com/dotnet/csharplang/blob/main/proposals/csharp-8.0/default-interface-methods.md> accordingly.

Pattern matching

Given the following code, a user might reasonably expect it to print True (as it would if the constant pattern was written inline):

```
C#  
  
M(1.0);  
  
static void M<T>(T t) where T : INumberBase<T>  
{  
    Console.WriteLine(t is 1);  
}
```

However, because the input type of the pattern is not `double`, the constant `1` pattern will first type check the incoming `T` against `int`. This is unintuitive, so we will block it until a future C# version adds better handling for numeric matching against types derived from `INumberBase<T>`. To do so, we will say that, we will explicitly recognize `INumberBase<T>` as the type that all "numbers" will derive from, and block the pattern if we're trying to match a numeric constant pattern against a number type that we can't represent the pattern in (ie, a type parameter constrained to `INumberBase<T>`, or a user-defined number type that inherits from `INumberBase<T>`).

Formally, we add an exception to the definition of *pattern-compatible* for constant patterns:

A constant pattern tests the value of an expression against a constant value. The constant may be any constant expression, such as a literal, the name of a declared `const` variable, or an enumeration constant. When the input value is not an open type, the constant expression is implicitly converted to the type of the matched expression; if the type of the input value is not *pattern-compatible* with the type of the constant expression, the pattern-matching operation is an error. **If the constant expression being matched against is a numeric value, the input value is a type that inherits from `System.Numerics.INumberBase<T>`, and there is no constant conversion from the constant expression to the type of the input value, the pattern-matching operation is an error.**

We also add a similar exception for relational patterns:

When the input is a type for which a suitable built-in binary relational operator is defined that is applicable with the input as its left operand and the given constant as its right operand, the evaluation of that operator is taken as the meaning of the relational pattern. Otherwise we convert the input to the type of the expression using an explicit nullable or unboxing conversion. It is a compile-time error if no such conversion exists. **It is a compile-time error if the input type is a type parameter constrained to or a type inheriting from `System.Numerics.INumberBase<T>` and the input type has no suitable built-in binary relational operator defined.** The pattern is considered not to match if the conversion fails. If the conversion succeeds then the result of the pattern-matching operation is the result of evaluating the expression $e \text{ OP } v$ where e is the converted input, OP is the relational operator, and v is the constant expression.

Drawbacks

- "static abstract" is a new concept and will meaningfully add to the conceptual load of C#.
- It's not a cheap feature to build. We should make sure it's worth it.

Alternatives

Structural constraints

An alternative approach would be to have "structural constraints" directly and explicitly requiring the presence of specific operators on a type parameter. The drawbacks of that are: - This would have to be written out every time. Having a named constraint seems better. - This is a whole new kind of constraint, whereas the proposed feature utilizes the existing concept of interface constraints. - It would only work for operators, not (easily) other kinds of static members.

Unresolved questions

Static abstract interfaces and static classes

Checked user-defined operators

Article • 2022-09-27 • 28 minutes to read

Summary

C# should support defining `checked` variants of the following user-defined operators so that users can opt into or out of overflow behavior as appropriate:

- The `++` and `--` unary operators [§11.7.14](#) and [§11.8.6](#).
- The `-` unary operator [§11.8.3](#).
- The `+`, `-`, `*`, and `/` binary operators [§11.9](#).
- Explicit conversion operators.

Motivation

There is no way for a user to declare a type and support both checked and unchecked versions of an operator. This will make it hard to port various algorithms to use the proposed `generic math` interfaces exposed by the libraries team. Likewise, this makes it impossible to expose a type such as `Int128` or `UInt128` without the language simultaneously shipping its own support to avoid breaking changes.

Detailed design

Syntax

Grammar at operators ([§14.10](#)) will be adjusted to allow `checked` keyword after the `operator` keyword right before the operator token:

```
antlr
```

```
overloadable_unary_operator
```

```
    : '+' | 'checked'? '-' | '!' | '~' | 'checked'? '++' | 'checked'? '--' |  
    'true' | 'false'  
    ;
```

```
overloadable_binary_operator
```

```
    : 'checked'? '+' | 'checked'? '-' | 'checked'? '*' | 'checked'?  
    '/' | '%' | '&' | '|' | '^' | '<<' |  
    right_shift | '==' | '!=' | '>' | '<' | '>=' | '<='  
    ;
```

```
conversion_operator_declarator
: 'implicit' 'operator' type '(' type identifier ')'
| 'explicit' 'operator' 'checked'? type '(' type identifier ')'
;
```

For example:

C#

```
public static T operator checked ++(T x) {...}
public static T operator checked --(T x) {...}
public static T operator checked -(T x) {...}
public static T operator checked +(T lhs, T rhs) {...}
public static T operator checked -(T lhs, T rhs) {...}
public static T operator checked *(T lhs, T rhs) {...}
public static T operator checked /(T lhs, T rhs) {...}
public static explicit operator checked U(T x) {...}
```

C#

```
public static T I1.operator checked ++(T x) {...}
public static T I1.operator checked --(T x) {...}
public static T I1.operator checked -(T x) {...}
public static T I1.operator checked +(T lhs, T rhs) {...}
public static T I1.operator checked -(T lhs, T rhs) {...}
public static T I1.operator checked *(T lhs, T rhs) {...}
public static T I1.operator checked /(T lhs, T rhs) {...}
public static explicit I1.operator checked U(T x) {...}
```

For brevity below, an operator with the `checked` keyword is referred to as a `checked operator` and an operator without it is referred to as a `regular operator`. These terms are not applicable to operators that don't have a `checked` form.

Semantics

A user-defined `checked operator` is expected to throw an exception when the result of an operation is too large to represent in the destination type. What does it mean to be too large actually depends on the nature of the destination type and is not prescribed by the language. Typically the exception thrown is a `System.OverflowException`, but the language doesn't have any specific requirements regarding this.

A user-defined `regular operator` is expected to not throw an exception when the result of an operation is too large to represent in the destination type. Instead, it is expected to return an instance representing a truncated result. What does it mean to be too large

and to be truncated actually depends on the nature of the destination type and is not prescribed by the language.

All existing user-defined operators out there that will have `checked` form supported fall into the category of `regular operators`. It is understood that many of them are likely to not follow the semantics specified above, but for the purpose of semantic analysis, compiler will assume that they are.

Checked vs. unchecked context within a `checked operator`

Checked/unchecked context within the body of a `checked operator` is not affected by the presence of the `checked` keyword. In other words, the context is the same as immediately at the beginning of the operator declaration. The developer would need to explicitly switch the context if part of their algorithm cannot rely on default context.

Names in metadata

Section "I.10.3.1 Unary operators" of ECMA-335 will be adjusted to include *op_CheckedIncrement*, *op_CheckedDecrement*, *op_CheckedUnaryNegation* as the names for methods implementing checked `++`, `--` and `-` unary operators.

Section "I.10.3.2 Binary operators" of ECMA-335 will be adjusted to include *op_CheckedAddition*, *op_CheckedSubtraction*, *op_CheckedMultiply*, *op_CheckedDivision* as the names for methods implementing checked `+`, `-`, `*`, and `/` binary operators.

Section "I.10.3.3 Conversion operators" of ECMA-335 will be adjusted to include *op_CheckedExplicit* as the name for a method implementing checked explicit conversion operator.

Unary operators

Unary `checked operators` follow the rules from [§14.10.2](#).

Also, a `checked operator` declaration requires a pair-wise declaration of a `regular operator` (the return type should match as well). A compile-time error occurs otherwise.

```
C#
```

```
public struct Int128
{
    // This is fine, both a checked and regular operator are defined
    public static Int128 operator checked -(Int128 lhs);
    public static Int128 operator -(Int128 lhs);
}
```

```

// This is fine, only a regular operator is defined
public static Int128 operator --(Int128 lhs);

// This should error, a regular operator must also be defined
public static Int128 operator checked ++(Int128 lhs);
}

```

Binary operators

Binary `checked operators` follow the rules from [§14.10.3](#).

Also, a `checked operator` declaration requires a pair-wise declaration of a `regular operator` (the return type should match as well). A compile-time error occurs otherwise.

```

C#

public struct Int128
{
    // This is fine, both a checked and regular operator are defined
    public static Int128 operator checked +(Int128 lhs, Int128 rhs);
    public static Int128 operator +(Int128 lhs, Int128 rhs);

    // This is fine, only a regular operator is defined
    public static Int128 operator -(Int128 lhs, Int128 rhs);

    // This should error, a regular operator must also be defined
    public static Int128 operator checked *(Int128 lhs, Int128 rhs);
}

```

Candidate user-defined operators

The <https://github.com/dotnet/csharplang/blob/main/spec/expressions.md#candidate-user-defined-operators> section will be adjusted as follows (additions/changes are in bold).

Given a type `T` and an operation `operator op(A)`, where `op` is an overloadable operator and `A` is an argument list, the set of candidate user-defined operators provided by `T` for `operator op(A)` is determined as follows:

- Determine the type `T0`. If `T` is a nullable type, `T0` is its underlying type, otherwise `T0` is equal to `T`.
- Find the set of user-defined operators, `U`. This set consists of:
 - In `unchecked` evaluation context, all regular `operator op` declarations in `T0`.

- In `checked` evaluation context, all checked and regular `operator op` declarations in `T0` except regular declarations that have pair-wise matching `checked operator` declaration.
- For all `operator op` declarations in `U` and all lifted forms of such operators, if at least one operator is applicable ([Applicable function member](#)) with respect to the argument list `A`, then the set of candidate operators consists of all such applicable operators in `T0`.
- Otherwise, if `T0` is `object`, the set of candidate operators is empty.
- Otherwise, the set of candidate operators provided by `T0` is the set of candidate operators provided by the direct base class of `T0`, or the effective base class of `T0` if `T0` is a type parameter.

Similar rules will be applied while determining the set of candidate operators in interfaces <https://github.com/dotnet/csharp-lang/blob/main/meetings/2017/LDM-2017-06-27.md#shadowing-within-interfaces>.

The section [§11.7.18](#) will be adjusted to reflect the effect that the checked/unchecked context has on unary and binary operator overload resolution.

Example #1:

```
C#

public class MyClass
{
    public static void Add(Int128 lhs, Int128 rhs)
    {
        // Resolves to `op_CheckedAddition`
        Int128 r1 = checked(lhs + rhs);

        // Resolves to `op_Addition`
        Int128 r2 = unchecked(lhs + rhs);

        // Resolve to `op_Subtraction`
        Int128 r3 = checked(lhs - rhs);

        // Resolve to `op_Subtraction`
        Int128 r4 = unchecked(lhs - rhs);

        // Resolves to `op_CheckedMultiply`
        Int128 r5 = checked(lhs * rhs);

        // Error: Operator '*' cannot be applied to operands of type
        // 'Int128' and 'Int128'
        Int128 r6 = unchecked(lhs * rhs);
    }
}
```

```

public static void Divide(Int128 lhs, byte rhs)
{
    // Resolves to `op_Division` - it is a better match than
    `op_CheckedDivision`
    Int128 r4 = checked(lhs / rhs);
}

public struct Int128
{
    public static Int128 operator checked +(Int128 lhs, Int128 rhs);
    public static Int128 operator +(Int128 lhs, Int128 rhs);

    public static Int128 operator -(Int128 lhs, Int128 rhs);

    // Cannot be declared in C#, but could be declared by some other
    language
    public static Int128 operator checked *(Int128 lhs, Int128 rhs);

    // Cannot be declared in C#, but could be declared by some other
    language
    public static Int128 operator checked /(Int128 lhs, int rhs);

    public static Int128 operator /(Int128 lhs, byte rhs);
}

```

Example #2:

```

C#

class C
{
    static void Add(C2 x, C3 y)
    {
        object o;

        // error CS0034: Operator '+' is ambiguous on operands of type 'C2'
        and 'C3'
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    // Cannot be declared in C#, but could be declared by some other
    language
    public static C1 operator checked + (C1 x, C3 y) => new C3();
}

```

```

class C2 : C1
{
    public static C2 operator + (C2 x, C1 y) => new C2();
}

class C3 : C1
{
}

```

Example #3:

```

C#

class C
{
    static void Add(C2 x, C3 y)
    {
        object o;

        // error CS0034: Operator '+' is ambiguous on operands of type 'C2'
        // and 'C3'
        o = checked(x + y);

        // C1.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    public static C1 operator + (C1 x, C3 y) => new C3();
}

class C2 : C1
{
    // Cannot be declared in C#, but could be declared by some other
    // language
    public static C2 operator checked + (C2 x, C1 y) => new C2();
}

class C3 : C1
{
}

```

Conversion operators

Conversion `checked operators` follow the rules from [§14.10.4](#).

However, a `checked operator` declaration requires a pair-wise declaration of a `regular operator`. A compile-time error occurs otherwise.

The following paragraph

The signature of a conversion operator consists of the source type and the target type. (This is the only form of member for which the return type participates in the signature.) The implicit or explicit classification of a conversion operator is not part of the operator's signature. Thus, a class or struct cannot declare both an implicit and an explicit conversion operator with the same source and target types.

will be adjusted to allow a type to declare checked and regular forms of explicit conversions with the same source and target types. A type will not be allowed to declare both an implicit and a checked explicit conversion operator with the same source and target types.

Processing of user-defined explicit conversions

The third bullet in [§10.5.5](#):

- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of the user-defined and lifted implicit or explicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.

will be replaced with the following bullet points:

- **Find the set of conversion operators, `U0`. This set consists of:**
 - In `unchecked` evaluation context, the user-defined implicit or regular explicit conversion operators declared by the classes or structs in `D`.
 - In `checked` evaluation context, the user-defined implicit or regular/checked explicit conversion operators declared by the classes or structs in `D` except regular explicit conversion operators that have pair-wise matching `checked operator` declaration within the same declaring type.
- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of the user-defined and lifted implicit or explicit conversion operators in `U0` that convert from a type encompassing or encompassed by `S` to a type

encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.

The Checked and unchecked operators §11.7.18 section will be adjusted to reflect the effect that the checked/unchecked context has on processing of user-defined explicit conversions.

Implementing operators

A `checked operator` does not implement a `regular operator` and vice versa.

Linq Expression Trees

`Checked operators` will be supported in Linq Expression Trees. A

UnaryExpression/BinaryExpression node will be created with corresponding `MethodInfo`.

The following factory methods will be used:

```
C#
```

```
public static UnaryExpression NegateChecked (Expression expression,
MethodInfo? method);

public static BinaryExpression AddChecked (Expression left, Expression
right, MethodInfo? method);
public static BinaryExpression SubtractChecked (Expression left, Expression
right, MethodInfo? method);
public static BinaryExpression MultiplyChecked (Expression left, Expression
right, MethodInfo? method);

public static UnaryExpression ConvertChecked (Expression expression, Type
type, MethodInfo? method);
```

Note, that C# doesn't support assignments in expression trees, therefore checked increment/decrement will not be supported as well.

There is no factory method for checked divide. There is an open question regarding this - [Checked division in Linq Expression Trees](#).

Dynamic

We will investigate the cost of adding support for checked operators in dynamic invocation in CoreCLR and pursue an implementation if the cost is not too high. This is a quote from <https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-02-09.md>.

Drawbacks

This adds additional complexity to the language and allows users to introduce more kinds of breaking changes to their types.

Alternatives

The generic math interfaces that the libraries plans to expose could expose named methods (such as `AddChecked`). The primary drawback is that this is less readable/maintainable and doesn't get the benefit of the language precedence rules around operators.

Placement of the `checked` keyword

Alternatively the `checked` keyword could be moved to the place right before the `operator` keyword:

C#

```
public static T checked operator ++(T x) {...}
public static T checked operator --(T x) {...}
public static T checked operator -(T x) {...}
public static T checked operator +(T lhs, T rhs) {...}
public static T checked operator -(T lhs, T rhs) {...}
public static T checked operator *(T lhs, T rhs) {...}
public static T checked operator /(T lhs, T rhs) {...}
public static explicit checked operator U(T x) {...}
```

C#

```
public static T checked I1.operator ++(T x) {...}
public static T checked I1.operator --(T x) {...}
public static T checked I1.operator -(T x) {...}
public static T checked I1.operator +(T lhs, T rhs) {...}
public static T checked I1.operator -(T lhs, T rhs) {...}
public static T checked I1.operator *(T lhs, T rhs) {...}
public static T checked I1.operator /(T lhs, T rhs) {...}
public static explicit checked I1.operator U(T x) {...}
```

Or it could be moved into the set of operator modifiers:

antlr

```
operator_modifier
: 'public'
```

```
| 'static'  
| 'extern'  
| 'checked'  
| operator_modifier_unsafe  
;
```

C#

```
public static checked T operator ++(T x) {...}  
public static checked T operator --(T x) {...}  
public static checked T operator -(T x) {...}  
public static checked T operator +(T lhs, T rhs) {...}  
public static checked T operator -(T lhs, T rhs) {...}  
public static checked T operator *(T lhs, T rhs) {...}  
public static checked T operator /(T lhs, T rhs) {...}  
public static checked explicit operator U(T x) {...}
```

C#

```
public static checked T I1.operator ++(T x) {...}  
public static checked T I1.operator --(T x) {...}  
public static checked T I1.operator -(T x) {...}  
public static checked T I1.operator +(T lhs, T rhs) {...}  
public static checked T I1.operator -(T lhs, T rhs) {...}  
public static checked T I1.operator *(T lhs, T rhs) {...}  
public static checked T I1.operator /(T lhs, T rhs) {...}  
public static checked explicit I1.operator U(T x) {...}
```

unchecked keyword

There were suggestions to support `unchecked` keyword at the same position as the `checked` keyword with the following possible meanings:

- Simply to explicitly reflect the regular nature of the operator, or
- Perhaps to designate a distinct flavor of an operator that is supposed to be used in an `unchecked` context. The language could support `op_Addition`, `op_CheckedAddition`, and `op_UncheckedAddition` to help limit the number of breaking changes. This adds another layer of complexity that is likely not necessary in most code.

Operator names in ECMA-335

Alternatively the operator names could be `op_UnaryNegationChecked`, `op_AdditionChecked`, `op_SubtractionChecked`, `op_MultiplyChecked`, `op_DivisionChecked`, with `Checked` at the end. However, it looks like there is already a pattern established to

end the names with the operator word. For example, there is a *op_UnsignedRightShift* operator rather than *op_RightShiftUnsigned* operator.

Checked operators are inapplicable in an unchecked context

The compiler, when performing member lookup to find candidate user-defined operators within an `unchecked` context, could ignore `checked operators`. If metadata is encountered that only defines a `checked operator`, then a compilation error will occur.

C#

```
public class MyClass
{
    public static void Add(Int128 lhs, Int128 rhs)
    {
        // Resolves to `op_CheckedMultiply`
        Int128 r5 = checked(lhs * rhs);

        // Error: Operator '*' cannot be applied to operands of type
        // 'Int128' and 'Int128'
        Int128 r5 = unchecked(lhs * rhs);
    }
}

public struct Int128
{
    public static Int128 operator checked *(Int128 lhs, Int128 rhs);
}
```

More complicated operator lookup and overload resolution rules in a checked context

The compiler, when performing member lookup to find candidate user-defined operators within a `checked` context will also consider applicable operators ending with `checked`. That is, if the compiler was attempting to find applicable function members for the binary addition operator, it would look for both `op_Addition` and `op_AdditionChecked`. If the only applicable function member is a `checked operator`, it will be used. If both a `regular operator` and `checked operator` exist and are equally applicable the `checked operator` will be preferred. If both a `regular operator` and a `checked operator` exist but the `regular operator` is an exact match while the `checked operator` is not, the compiler will prefer the `regular operator`.

C#

```

public class MyClass
{
    public static void Add(Int128 lhs, Int128 rhs)
    {
        // Resolves to `op_CheckedAddition`
        Int128 r1 = checked(lhs + rhs);

        // Resolves to `op_Addition`
        Int128 r2 = unchecked(lhs + rhs);

        // Resolve to `op_Subtraction`
        Int128 r3 = checked(lhs - rhs);

        // Resolve to `op_Subtraction`
        Int128 r4 = unchecked(lhs - rhs);
    }

    public static void Multiply(Int128 lhs, byte rhs)
    {
        // Resolves to `op_Multiply` even though `op_CheckedMultiply` is
        // also applicable
        Int128 r4 = checked(lhs * rhs);
    }
}

public struct Int128
{
    public static Int128 operator checked +(Int128 lhs, Int128 rhs);
    public static Int128 operator +(Int128 lhs, Int128 rhs);

    public static Int128 operator -(Int128 lhs, Int128 rhs);

    public static Int128 operator checked *(Int128 lhs, int rhs);
    public static Int128 operator *(Int128 lhs, byte rhs);
}

```

Yet another way to build the set of candidate user-defined operators

Unary operator overload resolution

Assuming that `regular operator` matches `unchecked` evaluation context, `checked operator` matches `checked` evaluation context and an operator that doesn't have `checked` form (for example, `+`) matches either context, the first bullet in

<https://github.com/dotnet/csharpplang/blob/main/spec/expressions.md#unary-operator-overload-resolution> ↗:

- The set of candidate user-defined operators provided by `X` for the operation `operator op(x)` is determined using the rules of [Candidate user-defined operators](#).

will be replaced with the following two bullet points:

- The set of candidate user-defined operators provided by `X` for the operation `operator op(x)` **matching the current checked/unchecked context** is determined using the rules of [Candidate user-defined operators](#).
- If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the set of candidate user-defined operators provided by `X` for the operation `operator op(x)` **matching the opposite checked/unchecked context** is determined using the rules of [Candidate user-defined operators](#).

Binary operator overload resolution

Assuming that `regular operator` matches `unchecked` evaluation context, `checked operator` matches `checked` evaluation context and an operator that doesn't have a `checked` form (for example, `%`) matches either context, the first bullet in <https://github.com/dotnet/csharpplang/blob/main/spec/expressions.md#binary-operator-overload-resolution>:

- The set of candidate user-defined operators provided by `X` and `Y` for the operation `operator op(x,y)` is determined. The set consists of the union of the candidate operators provided by `X` and the candidate operators provided by `Y`, each determined using the rules of [Candidate user-defined operators](#). If `X` and `Y` are the same type, or if `X` and `Y` are derived from a common base type, then shared candidate operators only occur in the combined set once.

will be replaced with the following two bullet points:

- The set of candidate user-defined operators provided by `X` and `Y` for the operation `operator op(x,y)` **matching the current checked/unchecked context** is determined. The set consists of the union of the candidate operators provided by `X` and the candidate operators provided by `Y`, each determined using the rules of [Candidate user-defined operators](#). If `X` and `Y` are the same type, or if `X` and `Y` are derived from a common base type, then shared candidate operators only occur in the combined set once.

- If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the set of candidate user-defined operators provided by `X` and `Y` for the operation `operator op(x,y)` **matching the opposite checked/unchecked context** is determined. The set consists of the union of the candidate operators provided by `X` and the candidate operators provided by `Y`, each determined using the rules of [Candidate user-defined operators](#). If `X` and `Y` are the same type, or if `X` and `Y` are derived from a common base type, then shared candidate operators only occur in the combined set once.

Example #1:

```
C#

public class MyClass
{
    public static void Add(Int128 lhs, Int128 rhs)
    {
        // Resolves to `op_CheckedAddition`
        Int128 r1 = checked(lhs + rhs);

        // Resolves to `op_Addition`
        Int128 r2 = unchecked(lhs + rhs);

        // Resolve to `op_Subtraction`
        Int128 r3 = checked(lhs - rhs);

        // Resolve to `op_Subtraction`
        Int128 r4 = unchecked(lhs - rhs);

        // Resolves to `op_CheckedMultiply`
        Int128 r5 = checked(lhs * rhs);

        // Resolves to `op_CheckedMultiply`
        Int128 r5 = unchecked(lhs * rhs);
    }

    public static void Divide(Int128 lhs, byte rhs)
    {
        // Resolves to `op_CheckedDivision`
        Int128 r4 = checked(lhs / rhs);
    }
}

public struct Int128
{
    public static Int128 operator checked +(Int128 lhs, Int128 rhs);
    public static Int128 operator +(Int128 lhs, Int128 rhs);

    public static Int128 operator -(Int128 lhs, Int128 rhs);
}
```

```

    public static Int128 operator checked *(Int128 lhs, Int128 rhs);

    public static Int128 operator checked /(Int128 lhs, int rhs);
    public static Int128 operator /(Int128 lhs, byte rhs);
}

```

Example #2:

```

C#

class C
{
    static void Add(C2 x, C3 y)
    {
        object o;

        // C1.op_CheckedAddition
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    public static C1 operator checked + (C1 x, C3 y) => new C3();
}

class C2 : C1
{
    public static C2 operator + (C2 x, C1 y) => new C2();
}

class C3 : C1
{
}

```

Example #3:

```

C#

class C
{
    static void Add(C2 x, C3 y)
    {
        object o;

        // C2.op_CheckedAddition

```

```

        o = checked(x + y);

        // C1.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    public static C1 operator + (C1 x, C3 y) => new C3();
}

class C2 : C1
{
    public static C2 operator checked + (C2 x, C1 y) => new C2();
}

class C3 : C1
{
}

```

Example #4:

```

C#

class C
{
    static void Add(C2 x, byte y)
    {
        object o;

        // C1.op_CheckedAddition
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }

    static void Add2(C2 x, int y)
    {
        object o;

        // C2.op_Addition
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
}

```

```

    public static C1 operator checked + (C1 x, byte y) => new C1();
}

class C2 : C1
{
    public static C2 operator + (C2 x, int y) => new C2();
}

```

Example #5:

```

C#

class C
{
    static void Add(C2 x, byte y)
    {
        object o;

        // C2.op_CheckedAddition
        o = checked(x + y);

        // C1.op_Addition
        o = unchecked(x + y);
    }

    static void Add2(C2 x, int y)
    {
        object o;

        // C1.op_Addition
        o = checked(x + y);

        // C1.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    public static C1 operator + (C1 x, int y) => new C1();
}

class C2 : C1
{
    public static C2 operator checked + (C2 x, byte y) => new C2();
}

```

Processing of user-defined explicit conversions

Assuming that `regular operator` matches `unchecked` evaluation context and `checked operator` matches `checked` evaluation context, the third bullet in <https://github.com/dotnet/csharp-lang/blob/main/spec/conversions.md#processing-of-user-defined-explicit-conversions>:

- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of the user-defined and lifted implicit or explicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.

will be replaced with the following bullet points:

- Find the set of applicable user-defined and lifted explicit conversion operators **matching the current checked/unchecked context**, `U0`. This set consists of the user-defined and lifted explicit conversion operators declared by the classes or structs in `D` that **match the current checked/unchecked context** and convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`.
- Find the set of applicable user-defined and lifted explicit conversion operators **matching the opposite checked/unchecked context**, `U1`. If `U0` is not empty, `U1` is empty. Otherwise, this set consists of the user-defined and lifted explicit conversion operators declared by the classes or structs in `D` that **match the opposite checked/unchecked context** and convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`.
- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of operators from `U0`, `U1`, and the user-defined and lifted implicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.

Yet another another way to build the set of candidate user-defined operators

Unary operator overload resolution

The first bullet in section [§11.4.4](#) will be adjusted as follows (additions are in bold).

- The set of candidate user-defined operators provided by `X` for the operation `operator op(x)` is determined using the rules of "Candidate user-defined operators" section below. **If the set contains at least one operator in checked form, all operators in regular form are removed from the set.**

The section [§11.7.18](#) will be adjusted to reflect the effect that the checked/unchecked context has on unary operator overload resolution.

Binary operator overload resolution

The first bullet in section [§11.4.5](#) will be adjusted as follows (additions are in bold).

- The set of candidate user-defined operators provided by `X` and `Y` for the operation `operator op(x,y)` is determined. The set consists of the union of the candidate operators provided by `X` and the candidate operators provided by `Y`, each determined using the rules of "Candidate user-defined operators" section below. If `X` and `Y` are the same type, or if `X` and `Y` are derived from a common base type, then shared candidate operators only occur in the combined set once. **If the set contains at least one operator in checked form, all operators in regular form are removed from the set.**

The Checked and unchecked operators [§11.7.18](#) section will be adjusted to reflect the effect that the checked/unchecked context has on binary operator overload resolution.

Candidate user-defined operators

The <https://github.com/dotnet/csharplang/blob/main/spec/expressions.md#candidate-user-defined-operators> section will be adjusted as follows (additions are in bold).

Given a type `T` and an operation `operator op(A)`, where `op` is an overloadable operator and `A` is an argument list, the set of candidate user-defined operators provided by `T` for `operator op(A)` is determined as follows:

- Determine the type `T0`. If `T` is a nullable type, `T0` is its underlying type, otherwise `T0` is equal to `T`.
- For all `operator op` declarations **in their checked and regular forms in checked evaluation context and only in their regular form in unchecked evaluation context** in `T0` and all lifted forms of such operators, if at least one operator is applicable ([Applicable function member](#)) with respect to the argument list `A`, then the set of candidate operators consists of all such applicable operators in `T0`.
- Otherwise, if `T0` is `object`, the set of candidate operators is empty.

- Otherwise, the set of candidate operators provided by `T0` is the set of candidate operators provided by the direct base class of `T0`, or the effective base class of `T0` if `T0` is a type parameter.

Similar filtering will be applied while determining the set of candidate operators in interfaces <https://github.com/dotnet/csharp-lang/blob/main/meetings/2017/LDM-2017-06-27.md#shadowing-within-interfaces>.

The <https://github.com/dotnet/csharp-lang/blob/main/spec/expressions.md#the-checked-and-unchecked-operators> section will be adjusted to reflect the effect that the checked/unchecked context has on unary and binary operator overload resolution.

Example #1:

```
C#

public class MyClass
{
    public static void Add(Int128 lhs, Int128 rhs)
    {
        // Resolves to `op_CheckedAddition`
        Int128 r1 = checked(lhs + rhs);

        // Resolves to `op_Addition`
        Int128 r2 = unchecked(lhs + rhs);

        // Resolve to `op_Subtraction`
        Int128 r3 = checked(lhs - rhs);

        // Resolve to `op_Subtraction`
        Int128 r4 = unchecked(lhs - rhs);

        // Resolves to `op_CheckedMultiply`
        Int128 r5 = checked(lhs * rhs);

        // Error: Operator '*' cannot be applied to operands of type
        // 'Int128' and 'Int128'
        Int128 r5 = unchecked(lhs * rhs);
    }

    public static void Divide(Int128 lhs, byte rhs)
    {
        // Resolves to `op_CheckedDivision`
        Int128 r4 = checked(lhs / rhs);
    }
}

public struct Int128
{
    public static Int128 operator checked +(Int128 lhs, Int128 rhs);
}
```

```

public static Int128 operator +(Int128 lhs, Int128 rhs);

public static Int128 operator -(Int128 lhs, Int128 rhs);

public static Int128 operator checked *(Int128 lhs, Int128 rhs);

public static Int128 operator checked /(Int128 lhs, int rhs);
public static Int128 operator /(Int128 lhs, byte rhs);
}

```

Example #2:

```

C#

class C
{
    static void Add(C2 x, C3 y)
    {
        object o;

        // C1.op_CheckedAddition
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    public static C1 operator checked + (C1 x, C3 y) => new C3();
}

class C2 : C1
{
    public static C2 operator + (C2 x, C1 y) => new C2();
}

class C3 : C1
{
}

```

Example #3:

```

C#

class C
{
    static void Add(C2 x, C3 y)
    {

```

```

    object o;

    // C2.op_CheckedAddition
    o = checked(x + y);

    // C1.op_Addition
    o = unchecked(x + y);
}
}

class C1
{
    public static C1 operator + (C1 x, C3 y) => new C3();
}

class C2 : C1
{
    public static C2 operator checked + (C2 x, C1 y) => new C2();
}

class C3 : C1
{
}

```

Example #4:

```

C#

class C
{
    static void Add(C2 x, byte y)
    {
        object o;

        // C2.op_Addition
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }

    static void Add2(C2 x, int y)
    {
        object o;

        // C2.op_Addition
        o = checked(x + y);

        // C2.op_Addition
        o = unchecked(x + y);
    }
}

```

```

class C1
{
    public static C1 operator checked + (C1 x, byte y) => new C1();
}

class C2 : C1
{
    public static C2 operator + (C2 x, int y) => new C2();
}

```

Example #5:

C#

```

class C
{
    static void Add(C2 x, byte y)
    {
        object o;

        // C2.op_CheckedAddition
        o = checked(x + y);

        // C1.op_Addition
        o = unchecked(x + y);
    }

    static void Add2(C2 x, int y)
    {
        object o;

        // C1.op_Addition
        o = checked(x + y);

        // C1.op_Addition
        o = unchecked(x + y);
    }
}

class C1
{
    public static C1 operator + (C1 x, int y) => new C1();
}

class C2 : C1
{
    public static C2 operator checked + (C2 x, byte y) => new C2();
}

```

Processing of user-defined explicit conversions

The third bullet in [§10.5.5](#):

- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of the user-defined and lifted implicit or explicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.

will be replaced with the following bullet points:

- Find the set of applicable user-defined and lifted explicit conversion operators, `U0`. This set consists of the user-defined and lifted explicit conversion operators declared by the classes or structs in `D` **in their checked and regular forms in checked evaluation context and only in their regular form in unchecked evaluation context** and convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`.
- If `U0` contains at least one operator in checked form, all operators in regular form are removed from the set.
- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of operators from `U0`, and the user-defined and lifted implicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.

The Checked and unchecked operators [§11.7.18](#) section will be adjusted to reflect the effect that the checked/unchecked context has on processing of user-defined explicit conversions.

Checked vs. unchecked context within a checked operator

The compiler could treat the default context of a checked operator as checked. The developer would need to explicitly use unchecked if part of their algorithm should not participate in the checked context. However, this might not work well in the future if we start allowing checked/unchecked tokens as modifiers on operators to set the context within the body. The modifier and the keyword could contradict each other. Also, we wouldn't be able to do the same (treat default context as unchecked) for a regular operator because that would be a breaking change.

Unresolved questions

Should the language allow `checked` and `unchecked` modifiers on methods (e.g. `static checked void M()`)? This would allow removing nesting levels for methods that require it.

Checked division in Linq Expression Trees

There is no factory method to create a checked division node and there is no `ExpressionType.DivideChecked` member. We could still use the following factory method to create regular divide node with `MethodInfo` pointing to the `op_CheckedDivision` method. Consumers will have to check the name to infer the context.

C#

```
public static BinaryExpression Divide (Expression left, Expression right,
MethodInfo? method);
```

Note, even though §11.7.18 [↗](#) section lists `/` operator as one of the operators affected by checked/unchecked evaluation context, IL doesn't have a special op code to perform checked division. Compiler always uses the factory method regardless of the context today.

Proposal: Checked user-defined division will not be supported in Linq Expression Trees.

(Resolved) Should we support implicit checked conversion operators?

In general, implicit conversion operators are not supposed to throw.

Proposal: No.

Resolution: Approved -

Unsigned right shift operator

Article • 2022-09-27 • 5 minutes to read

Summary

An unsigned right shift operator will be supported by C# as a built-in operator (for primitive integral types) and as a user-defined operator.

Motivation

When working with signed integral value, it is not uncommon that you need to shift bits right without replicating the high order bit on each shift. While this can be achieved for primitive integral types with a regular shift operator, a cast to an unsigned type before the shift operation and a cast back after it is required. Within the context of the generic math interfaces the libraries are planning to expose, this is potentially more problematic as the type might not necessary have an unsigned counterpart defined or known upfront by the generic math code, yet an algorithm might rely on ability to perform an unsigned right shift operation.

Detailed design

Operators and punctuators

Section [§6.4.6](#) will be adjusted to include `>>>` operator - the unsigned right shift operator:

```
antlr

unsigned_right_shift
    : '>>>'
    ;

unsigned_right_shift_assignment
    : '>>>='
    ;
```

No characters of any kind (not even whitespace) are allowed between the tokens in *unsigned_right_shift* and *unsigned_right_shift_assignment* productions. These productions are treated specially in order to enable the correct handling of *type_parameter_lists*.

Shift operators

Section [§11.10](#) will be adjusted to include `>>>` operator - the unsigned right shift operator:

The `<<`, `>>` and `>>>` operators are used to perform bit shifting operations.

antlr

```
shift_expression
: additive_expression
| shift_expression '<<' additive_expression
| shift_expression right_shift additive_expression
| shift_expression unsigned_right_shift additive_expression
;
```

For an operation of the form `x << count` or `x >> count` or `x >>> count`, binary operator overload resolution ([§11.4.5](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined unsigned shift operators will support the same set of signatures that predefined signed shift operators support today in the current implementation.

- Shift right:

C#

```
int operator >>>(int x, int count);
uint operator >>>(uint x, int count);
long operator >>>(long x, int count);
ulong operator >>>(ulong x, int count);
nint operator >>>(nint x, int count);
nuint operator >>>(nuint x, int count);
```

The `>>>` operator shifts `x` right by a number of bits computed as described below.

The low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero.

For the predefined operators, the number of bits to shift is computed as follows:

- When the type of `x` is `int` or `uint`, the shift count is given by the low-order five bits of `count`. In other words, the shift count is computed from `count & 0x1F`.
- When the type of `x` is `long` or `ulong`, the shift count is given by the low-order six bits of `count`. In other words, the shift count is computed from `count & 0x3F`.

If the resulting shift count is zero, the shift operators simply return the value of `x`.

Shift operations never cause overflows and produce the same results in `checked` and `unchecked` contexts.

Assignment operators

Section [§11.18](#) will be adjusted to include *unsigned_right_shift_assignment* as follows:

```
antlr
assignment_operator
: '='
| '+='
| '-='
| '*='
| '/='
| '%='
| '&='
| '|='
| '^='
| '<<='
| right_shift_assignment
| unsigned_right_shift_assignment
;
```

Integral types

The Integral types [§8.3.6](#) section will be adjusted to include information about `>>>` operator. The relevant bullet point is the following:

- For the binary `<<`, `>>` and `>>>` operators, the left operand is converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`.

Constant expressions

Operator `>>>` will be added to the set of constructs permitted in constant expressions at [§11.20](#).

Operator overloading

Operator `>>>` will be added to the set of overloadable binary operators at [§11.4.3](#).

Lifted operators

Operator `>>>` will be added to the set of binary operators permitting a lifted form at [§11.4.8](#).

Operator precedence and associativity

Section [§11.4.2](#) will be adjusted to add `>>>` operator to the "Shift" category and `>>>=` operator to the "Assignment and lambda expression" category.

Grammar ambiguities

The `>>>` operator is subject to the same grammar ambiguities described at [§6.2.5](#) as a regular `>>` operator.

Operators

The [§14.10](#) section will be adjusted to include `>>>` operator.

```
antlr
```

```
overloadable_binary_operator
: '+' | '-' | '*' | '/' | '%' | '&' | '|' | '^' | '<<'
  | right_shift | unsigned_right_shift | '==' | '!=' | '>' | '<' |
  '>=' | '<='
;
```

Binary operators

The signature of a `>>>` operator is subject to the same rules as those at [§14.10.3](#) for the signature of a `>>` operator.

Metadata name

Section "I.10.3.2 Binary operators" of ECMA-335 already reserved the name for an unsigned right shift operator - `op_UnsignedRightShift`.

Linq Expression Trees

The `>>>` operator will not be supported in Linq Expression Trees because semantics of predefined `>>>` operators on signed types cannot be accurately represented without

adding conversions to an unsigned type and back. See <https://github.com/dotnet/csharp-lang/blob/main/meetings/2022/LDM-2022-02-09.md#unsigned-right-shift-operator> for more information.

Dynamic Binding

It looks like dynamic binding uses values of `System.Linq.Expressions.ExpressionType` enum to communicate binary operator kind to the runtime binder. Since we don't have a member specifically representing an unsigned right shift operator, dynamic binding for `>>>` operator will not be supported and the static and dynamic binding (§11.3) section will be adjusted to reflect that.

Drawbacks

Alternatives

Linq Expression Trees

The `>>>` operator will be supported in Linq Expression Trees.

- For a user-defined operator, a `BinaryExpression` node pointing to the operator method will be created.
- For predefined operators
 - when the first operand is an unsigned type, a `BinaryExpression` node will be created.
 - when the first operand is a signed type, a conversion for the first operand to an unsigned type will be added, a `BinaryExpression` node will be created and conversion for the result back to the signed type will be added.

For example:

```
C#
```

```
Expression<System.Func<int, int, int>> z = (x, y) => x >>> y; // (x, y) =>  
Convert((Convert(x, UInt32) >> y), Int32)
```

Resolution:

Rejected, see <https://github.com/dotnet/csharp-lang/blob/main/meetings/2022/LDM-2022-02-09.md#unsigned-right-shift-operator> for more information.

Unresolved questions

<https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-02-09.md> 

Relaxing shift operator requirements

Article • 2022-09-27 • 2 minutes to read

Summary

The shift operator requirements will be relaxed so that the right-hand side operand is no longer restricted to only be `int`.

Motivation

When working with types other than `int`, it is not uncommon that you shift using the result of another computation, such as shifting based on the `leading zero count`. The natural type of something like a `leading zero count` is the same as the input type (`TSelf`) and so in many cases, this requires you to convert that result to `int` before shifting, even if that result is already within range.

Within the context of the generic math interfaces the libraries are planning to expose, this is potentially problematic as the type is not well known and so the conversion to `int` may not be possible or even well-defined.

Detailed design

Shift operators

[§11.10](#) should be reworded as follows:

diff

- When declaring an overloaded shift operator, the type of the first operand must always be the class or struct containing the operator declaration, and the type of the second operand must always be `int`.
- + When declaring an overloaded shift operator, the type of the first operand must always be the class or struct containing the operator declaration.

That is, the restriction that the first operand be the class or struct containing the operator declaration remains. While the restriction that the second operand must be `int` is removed.

Binary operators

§14.10.3 [↗](#) should be reworded as follows:

diff

```
-* A binary `<<` or `>>` operator must take two parameters, the first of which must have type `T` or `T?` and the second of which must have type `int` or `int?`, and can return any type.
```

```
+* A binary `<<` or `>>` operator must take two parameters, the first of which must have type `T` or `T?`, and can return any type.
```

That is, the restriction that the first parameter be `T` or `T?` remains. While the restriction that the second operand must be `int` or `int?` is removed.

Binary operator overload resolution

The first bullet point at §11.4.5 [↗](#) should be reworded as follows:

- The set of candidate user-defined operators provided by `X` and `Y` for the operation `operator op(x,y)` is determined. The set consists of the union of the candidate operators provided by `X` and `Y`, **unless the operator is a shift operator**, the candidate operators provided by `Y`, each determined using the rules of Candidate user-defined operators §11.4.6 [↗](#). If `X` and `Y` are the same type, or if `X` and `Y` are derived from a common base type, then shared candidate operators only occur in the combined set once.

That is, for shift operators, candidate operators are only those provided by type `X`.

Drawbacks

Users will be able to define operators that do not follow the recommended guidelines, such as implementing `cout << "string"` in C#.

Alternatives

The generic math interfaces being exposed by the libraries could expose explicitly named methods instead. This may make code more difficult to read/maintain.

The generic math interfaces could require the shift take `int` and that a conversion be performed. This conversion may be expensive or may be not possible depending on the type in question.

Unresolved questions

Is there concern around preserving the "intent" around why the second operand was restricted to `int`?

Numeric IntPtr

Article • 2022-09-29 • 10 minutes to read

Summary

This is a revision on the initial native integers feature ([spec](#)), where the `nint/nuint` types were distinct from the underlying types `System.IntPtr/System.UIntPtr`. In short, we now treat `nint/nuint` as simple types aliasing `System.IntPtr/System.UIntPtr`, like we do for `int` in relation to `System.Int32`. The

`System.Runtime.CompilerServices.RuntimeFeature.NumericIntPtr` runtime feature flag triggers this new behavior.

Design

8.3.5 Simple types

C# provides a set of predefined `struct` types called the simple types. The simple types are identified through keywords, but these keywords are simply aliases for predefined `struct` types in the `System` namespace, as described in the table below.

Keyword	Aliased type
<code>sbyte</code>	<code>System.SByte</code>
<code>byte</code>	<code>System.Byte</code>
<code>short</code>	<code>System.Int16</code>
<code>ushort</code>	<code>System.UInt16</code>
<code>int</code>	<code>System.Int32</code>
<code>uint</code>	<code>System.UInt32</code>
<code>nint</code>	<code>System.IntPtr</code>
<code>nuint</code>	<code>System.UIntPtr</code>
<code>long</code>	<code>System.Int64</code>
<code>ulong</code>	<code>System.UInt64</code>
<code>char</code>	<code>System.Char</code>

Keyword	Aliased type
<code>float</code>	<code>System.Single</code>
<code>double</code>	<code>System.Double</code>
<code>bool</code>	<code>System.Boolean</code>
<code>decimal</code>	<code>System.Decimal</code>

[...]

8.3.6 Integral types

C# supports eleven integral types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, and `char`. [...]

8.8 Unmanaged types

In other words, an *unmanaged_type* is one of the following:

- `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, or `bool`.
- Any *enum_type*.
- Any user-defined *struct_type* that is not a constructed type and contains fields of *unmanaged_types* only.
- In unsafe code, any *pointer_type*.

10.2.3 Implicit numeric conversions

The implicit numeric conversions are:

- From `sbyte` to `short`, `int`, `nint`, `long`, `float`, `double`, or `decimal`.
- From `byte` to `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `short` to `int`, `nint`, `long`, `float`, `double`, or `decimal`.
- From `ushort` to `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `int` to `nint`, `long`, `float`, `double`, or `decimal`.
- From `uint` to `nuint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `nint` to `long`, `float`, `double`, or `decimal`.
- From `nuint` to `ulong`, `float`, `double`, or `decimal`.

- From `long` to `float`, `double`, or `decimal`.
- From `ulong` to `float`, `double`, or `decimal`.
- From `char` to `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `float` to `double`.

[...]

10.2.11 Implicit constant expression conversions

An implicit constant expression conversion permits the following conversions:

- A *constant_expression* of type `int` can be converted to type `sbyte`, `byte`, `short`, `ushort`, `uint`, `nint`, `nuint`, or `ulong`, provided the value of the *constant_expression* is within the range of the destination type. [...]

10.3.2 Explicit numeric conversions

The explicit numeric conversions are the conversions from a *numeric_type* to another *numeric_type* for which an implicit numeric conversion does not already exist:

- From `sbyte` to `byte`, `ushort`, `uint`, `nuint`, `ulong`, or `char`.
- From `byte` to `sbyte` or `char`.
- From `short` to `sbyte`, `byte`, `ushort`, `uint`, `nuint`, `ulong`, or `char`.
- From `ushort` to `sbyte`, `byte`, `short`, or `char`.
- From `int` to `sbyte`, `byte`, `short`, `ushort`, `uint`, `nuint`, `ulong`, or `char`.
- From `uint` to `sbyte`, `byte`, `short`, `ushort`, `int`, `nint`, or `char`.
- From `long` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `ulong`, or `char`.
- From `nint` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nuint`, `ulong`, or `char`.
- From `nuint` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `long`, or `char`.
- From `ulong` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, or `char`.
- From `char` to `sbyte`, `byte`, or `short`.
- From `float` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, or `decimal`.
- From `double` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, or `decimal`.
- From `decimal` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, or `double`.

[...]

10.3.3 Explicit enumeration conversions

The explicit enumeration conversions are:

- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, or `decimal` to any *enum_type*.
- From any *enum_type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, or `decimal`.
- From any *enum_type* to any other *enum_type*.

11.6.4.6 Better conversion target

Given two types `T1` and `T2`, `T1` is a **better conversion target** than `T2` if one of the following holds:

- An implicit conversion from `T1` to `T2` exists and no implicit conversion from `T2` to `T1` exists
- `T1` is `Task<S1>`, `T2` is `Task<S2>`, and `S1` is a better conversion target than `S2`
- `T1` is `S1` or `S1?` where `S1` is a signed integral type, and `T2` is `S2` or `S2?` where `S2` is an unsigned integral type. Specifically: [...]

11.7.10 Element access

[...] The number of expressions in the *argument_list* shall be the same as the rank of the *array_type*, and each expression shall be of type `int`, `uint`, `nint`, `nuint`, `long`, or `ulong`, or shall be implicitly convertible to one or more of these types.

11.7.10.2 Array access

[...] The number of expressions in the *argument_list* shall be the same as the rank of the *array_type*, and each expression shall be of type `int`, `uint`, `nint`, `nuint`, `long`, or `ulong`, or shall be implicitly convertible to one or more of these types.

[...] The run-time processing of an array access of the form `P[A]`, where `P` is a *primary_no_array_creation_expression* of an *array_type* and `A` is an *argument_list*, consists of the following steps: [...]

- The index expressions of the *argument_list* are evaluated in order, from left to right. Following evaluation of each index expression, an implicit conversion to one of the following types is performed: `int`, `uint`, `nint`, `nuint`, `long`, `ulong`. The first type in this list for which an implicit conversion exists is chosen. [...]

11.7.14 Postfix increment and decrement operators

Unary operator overload resolution is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type.

11.8.2 Unary plus operator

The predefined unary plus operators are:

```
C#  
  
...  
nint operator +(nint x);  
nuint operator +(nuint x);
```

11.8.3 Unary minus operator

The predefined unary minus operators are:

- Integer negation:

```
C#  
  
...  
nint operator -(nint x);
```

11.7.14 Postfix increment and decrement operators

Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type.

11.7.19 Default value expressions

In addition, a *default_value_expression* is a constant expression if the type is one of the following value types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, or any enumeration type.

11.8.5 Bitwise complement operator

The predefined bitwise complement operators are:

```
C#  
  
...  
nint operator ~(nint x);  
nuint operator ~(nuint x);
```

11.8.6 Prefix increment and decrement operators

Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type.

11.9 Arithmetic operators

11.9.2 Multiplication operator

The predefined multiplication operators are listed below. The operators all compute the product of `x` and `y`.

- Integer multiplication:

```
C#  
  
...  
nint operator *(nint x, nint y);  
nuint operator *(nuint x, nuint y);
```

11.9.3 Division operator

The predefined division operators are listed below. The operators all compute the quotient of `x` and `y`.

- Integer division:

```
C#  
  
...  
nint operator /(nint x, nint y);  
nuint operator /(nuint x, nuint y);
```

11.9.4 Remainder operator

The predefined remainder operators are listed below. The operators all compute the remainder of the division between `x` and `y`.

- Integer remainder:

```
C#  
  
...  
nint operator %(nint x, nint y);  
nuint operator %(nuint x, nuint y);
```

11.9.5 Addition operator

- Integer addition:

```
C#  
  
...  
nint operator +(nint x, nint y);  
nuint operator +(nuint x, nuint y);
```

11.9.6 Subtraction operator

- Integer subtraction:

```
C#  
  
...  
nint operator -(nint x, nint y);  
nuint operator -(nuint x, nuint y);
```

11.10 Shift operators

The predefined shift operators are listed below.

- Shift left:

```
C#  
  
...  
nint operator <<(nint x, int count);  
nuint operator <<(nuint x, int count);
```

- Shift right:

```
C#  
  
...  
nint operator >>(nint x, int count);  
nuint operator >>(nuint x, int count);
```

The `>>` operator shifts `x` right by a number of bits computed as described below.

When `x` is of type `int`, `nint` or `long`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero if `x` is non-negative and set to one if `x` is negative.

When `x` is of type `uint`, `nuint` or `ulong`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero.

- Unsigned shift right:

```
C#  
  
...  
nint operator >>>(nint x, int count);  
nuint operator >>>(nuint x, int count);
```

For the predefined operators, the number of bits to shift is computed as follows: [...]

- When the type of `x` is `nint` or `nuint`, the shift count is given by the low-order five bits of `count` on a 32 bit platform, or the lower-order six bits of `count` on a 64 bit platform.

11.11 Relational and type-testing operators

11.11.2 Integer comparison operators

The predefined integer comparison operators are:

```
C#  
  
...  
bool operator ==(nint x, nint y);  
bool operator ==(nuint x, nuint y);
```

```

bool operator !=(nint x, nint y);
bool operator !=(nuint x, nuint y);

bool operator <(nint x, nint y);
bool operator <(nuint x, nuint y);

bool operator >(nint x, nint y);
bool operator >(nuint x, nuint y);

bool operator <=(nint x, nint y);
bool operator <=(nuint x, nuint y);

bool operator >=(nint x, nint y);
bool operator >=(nuint x, nuint y);

```

11.12 Logical operators

11.12.2 Integer logical operators

The predefined integer logical operators are:

```

C#

...
nint operator &(nint x, nint y);
nuint operator &(nuint x, nuint y);

nint operator |(nint x, nint y);
nuint operator |(nuint x, nuint y);

nint operator ^(nint x, nint y);
nuint operator ^(nuint x, nuint y);

```

11.20 Constant expressions

A constant expression may be either a value type or a reference type. If a constant expression is a value type, it must be one of the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, or any enumeration type.

[...]

An implicit constant expression conversion permits a constant expression of type `int` to be converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, `nint`, `nuint`, or `ulong`, provided the

value of the constant expression is within the range of the destination type.

16.4 Array element access

Array elements are accessed using *element_access* expressions of the form `A[I1, I2, ..., Ix]`, where `A` is an expression of an array type and each `Ie` is an expression of type `int`, `uint`, `nint`, `nuint`, `long`, `ulong`, or can be implicitly converted to one or more of these types. The result of an array element access is a variable, namely the array element selected by the indices.

22.5 Pointer conversions

22.5.1 General

[...]

Additionally, in an unsafe context, the set of available explicit conversions is extended to include the following explicit pointer conversions:

- From any *pointer_type* to any other *pointer_type*.
- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, or `ulong` to any *pointer_type*.
- From any *pointer_type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `nint`, `nuint`, `long`, or `ulong`.

22.6.4 Pointer element access

[...] In a pointer element access of the form `P[E]`, `P` shall be an expression of a pointer type other than `void*`, and `E` shall be an expression that can be implicitly converted to `int`, `uint`, `nint`, `nuint`, `long`, or `ulong`.

22.6.7 Pointer arithmetic

In an unsafe context, the `+` operator and `-` operator can be applied to values of all pointer types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
[...]
T* operator +(T* x, nint y);
T* operator +(T* x, nuint y);
T* operator +(nint x, T* y);
T* operator +(nuint x, T* y);
T* operator -(T* x, nint y);
T* operator -(T* x, nuint y);
```

Given an expression `P` of a pointer type `T*` and an expression `N` of type `int`, `uint`, `nint`, `nuint`, `long`, or `ulong`, the expressions `P + N` and `N + P` compute the pointer value of type `T*` that results from adding `N * sizeof(T)` to the address given by `P`. Likewise, the expression `P - N` computes the pointer value of type `T*` that results from subtracting `N * sizeof(T)` from the address given by `P`.

Various considerations

Breaking changes

One of the main impacts of this design is that `System.IntPtr` and `System.UIntPtr` gain some built-in operators (conversions, unary and binary). Those include `checked` operators, which means that the following operators on those types will now throw when overflowing:

- `IntPtr + int`
- `IntPtr - int`
- `IntPtr -> int`
- `long -> IntPtr`
- `void* -> IntPtr`

Metadata encoding

This design means that `nint` and `nuint` can simply be emitted as `System.IntPtr` and `System.UIntPtr`, without the use of `System.Runtime.CompilerServices.NativeIntegerAttribute`.

Similarly, when loading metadata `NativeIntegerAttribute` can be ignored.

Raw string literal

Article • 2023-01-10 • 19 minutes to read

Summary

Allow a new form of string literal that starts with a minimum of three `"""` characters (but no maximum), optionally followed by a `new_line`, the content of the string, and then ends with the same number of quotes that the literal started with. For example:

```
var xml = """
    <element attr="content"/>
    """;
```

Because the nested contents might itself want to use `"""` then the starting/ending delimiters can be longer like so:

```
var xml = """
    Ok to use """ here
    """;
```

To make the text easy to read and allow for indentation that developers like in code, these string literals will naturally remove the indentation specified on the last line when producing the final literal value. For example, a literal of the form:

```
var xml = """
    <element attr="content">
        <body>
    </body>
    </element>
    """;
```

Will have the contents:

```
<element attr="content">
    <body>
```

```
</body>  
</element>
```

This allows code to look natural, while still producing literals that are desired, and avoiding runtime costs if this required the use of specialized string manipulation routines.

If the indentation behavior is not desired, it is also trivial to disable like so:

```
var xml = ""  
    <element attr="content">  
        <body>  
        </body>  
    </element>  
"";
```

A single line form is also supported. It starts with a minimum of three `"""` characters (but no maximum), the content of the string (which cannot contain any `new_line` characters), and then ends with the same number of quotes that the literal started with. For example:

```
var xml = """<summary><element attr="content"/></summary>""";
```

Interpolated raw strings are also supported. In this case, the string specifies the number of braces needed to start an interpolation (determined by the number of dollar signs present at the start of the literal). Any brace sequence with fewer braces than that is just treated as content. For example:

```
var json = $$""  
    {  
        "summary": "text",  
        "length" : {{value.Length}},  
    };  
""
```

Motivation

C# lacks a general way to create simple string literals that can contain effectively any arbitrary text. All C# string literal forms today need some form of escaping in case the contents use some special character (always if a delimiter is used). This prevents easily having literals containing other languages in them (for example, an XML, HTML or JSON literal).

All current approaches to form these literals in C# today always force the user to manually escape the contents. Editing at that point can be highly annoying as the escaping cannot be avoided and must be dealt with whenever it arises in the contents. This is particularly painful for regexes, especially when they contain quotes or backslashes. Even with a `@""` string, quotes themselves must be escaped leading to a mix of C# and regex interspersed. `{` and `}` are similarly frustrating in `$""` strings.

The crux of the problem is that all our strings have a fixed start/end delimiter. As long as that is the case, we will always have to have an escaping mechanism as the string contents may need to specify that end delimiter in their contents. This is particularly problematic as that delimiter `"` is exceedingly common in many languages.

To address this, this proposal allows for flexible start and end delimiters so that they can always be made in a way that will not conflict with the content of the string.

Goals

1. Provide a mechanism that will allow *all* string values to be provided by the user without the need for *any* escape-sequences whatsoever. Because all strings must be representable without escape-sequences, it must always be possible for the user to specify delimiters that will be guaranteed to not collide with any text contents.
2. Support interpolations in the same fashion. As above, because *all* strings must be representable without escapes, it must always be possible for the user to specify an `interpolation` delimiter that will be guaranteed to not collide with any text contents. Importantly, languages that use our `interpolation` delimiter characters (`{` and `}`) should feel first-class and not painful to use.
3. Multiline string literals should look pleasant in code and should not make indentation within the compilation unit look strange. Importantly, literal values that themselves have no indentation should not be forced to occupy the first column of the file as that can break up the flow of code and will look unaligned with the rest of the code that surrounds it.
 - This behavior should be easy to override while keeping literals clear and easy to read.

4. For all strings that do not themselves contain a `new_line` or start or end with a quote (") character, it should be possible to represent the string literal itself on a single line.

- Optionally, with extra complexity, we could refine this to state that: For all strings that do not themselves contain a `new_line` (but can start or end with a quote " character), it should be possible to represent the string literal itself on a single line. For more details see the expanded proposal in the `Drawbacks` section.

Detailed design (non-interpolation case)

We will add a new `string_literal` production with the following form:

```
string_literal
  : regular_string_literal
  | verbatim_string_literal
  | raw_string_literal
  ;

raw_string_literal
  : single_line_raw_string_literal
  | multi_line_raw_string_literal
  ;

raw_string_literal_delimiter
  : ""
  | ""
  | ""
  | etc.
  ;

raw_content
  : not_new_line+
  ;

single_line_raw_string_literal
  : raw_string_literal_delimiter raw_content raw_string_literal_delimiter
  ;

multi_line_raw_string_literal
  : raw_string_literal_delimiter whitespace* new_line (raw_content |
new_line)* new_line whitespace* raw_string_literal_delimiter
  ;

not_new_line
```

```
: <any unicode character that is not new_line>  
;
```

The ending delimiter to a `raw_string_literal` must match the starting delimiter. So if the starting delimiter is `""""""` the ending delimiter must be that as well.

The above grammar for a `raw_string_literal` should be interpreted as:

1. It starts with at least three quotes (but no upper bound on quotes).
2. It then continues with contents on the same line as the starting quotes. These contents on the same line can be blank, or non-blank. 'blank' is synonymous with 'entirely whitespace'.
3. If the contents on that same line is non-blank no further content can follow. In other words the literal is required to end with the same number of quotes on that same line.
4. If the contents on the same line is blank, then the literal can continue with a `new_line` and some number of subsequent content lines and `new_lines`.
 - A content line is any text except a `new_line`.
 - It then ends with a `new_line` some number (possibly zero) of `whitespace` and the same number of quotes that the literal started with.

Raw string literal value

The portions between the starting and ending `raw_string_literal_delimiter` are used to form the value of the `raw_string_literal` in the following fashion:

- In the case of `single_line_raw_string_literal` the value of the literal will exactly be the contents between the starting and ending `raw_string_literal_delimiter`.
- In the case of `multi_line_raw_string_literal` the initial `whitespace* new_line` and the final `new_line whitespace*` is not part of the value of the string. However, the final `whitespace*` portion preceding the `raw_string_literal_delimiter` terminal is considered the 'indentation whitespace' and will affect how the other lines are interpreted.
- To get the final value the sequence of `(raw_content | new_line)*` is walked and the following is performed:
 - If it is a `new_line` the content of the `new_line` is added to the final string value.
 - If it is not a 'blank' `raw_content` (i.e. `not_new_line+` contains a non-`whitespace` character):
 - the 'indentation whitespace' must be a prefix of the `raw_content`. It is an error otherwise.

- the 'indentation whitespace' is stripped from the start of `raw_content` and the remainder is added to the final string value.
- If it is a 'blank' `raw_content` (i.e. `not_new_line+` is entirely `whitespace`):
 - the 'indentation whitespace' must be a prefix of the `raw_content` or the `raw_content` must be a prefix of the 'indentation whitespace'. It is an error otherwise.
 - as much of the 'indentation whitespace' is stripped from the start of `raw_content` and any remainder is added to the final string value.

Clarifications:

1. A `single_line_raw_string_literal` is not capable of representing a string with a `new_line` value in it. A `single_line_raw_string_literal` does not participate in the 'indentation whitespace' trimming. Its value is always the exact characters between the starting and ending delimiters.
2. Because a `multi_line_raw_string_literal` ignores the final `new_line` of the last content line, the following represents a string with no starting `new_line` and no terminating `new_line`

```
var v1 = """
    This is the entire content of the string.
    """
```

This maintains symmetry with how the starting `new_line` is ignored, and it also provides a uniform way to ensure the 'indentation whitespace' can always be adjusted. To represent a string with a terminal `new_line` an extra line must be provided like so:

```
var v1 = """
    This string ends with a new line.

    """
```

3. A `single_line_raw_string_literal` cannot represent a string value that starts or ends with a quote (") though an augmentation to this proposal is provided in the `Drawbacks` section that shows how that could be supported.

4. A `multi_line_raw_string_literal` starts with `whitespace* new_line` following the initial `raw_string_literal_delimiter`. This content after the delimiter is entirely ignored and is not used in any way when determining the value of the string. This allows for a mechanism to specify a `raw_string_literal` whose content starts with a `"` character itself. For example:

```
var v1 = ""
    "The content of this string starts with a quote
    ""
```

5. A `raw_string_literal` can also represent content that end with a quote (`"`). This is supported as the terminating delimiter must be on its own line. For example:

```
var v1 = ""
    "The content of this string starts and ends with a quote"
    ""
```

```
var v1 = ""
    ""The content of this string starts and ends with two quotes""
    ""
```

5. The requirement that a 'blank' `raw_content` be either a prefix of the 'indentation whitespace' or the 'indentation whitespace' must be a prefix of it helps ensure confusing scenarios with mixed whitespace do not occur, especially as it would be unclear what should happen with that line. For example, the following case is illegal:

```
var v1 = ""
    Start
<tab>
    End
    ""
```

6. Here the 'indentation whitespace' is nine space characters, but the 'blank' `raw_content` does not start with a prefix of that. There is no clear answer as to how that `<tab>` line should be treated at all. Should it be ignored? Should it be the

same as<tab>? As such, making it illegal seems the clearest for avoiding confusion.

7. The following cases are legal though and represent the same string:

```
var v1 = ""
    Start
<four spaces>
    End
    ""
```

```
var v1 = ""
    Start
<nine spaces>
    End
    ""
```

In both these cases, the 'indentation whitespace' will be nine spaces. And in both cases, we will remove as much of that prefix as possible, leading the 'blank' `raw_content` in each case to be empty (not counting every `new_line`). This allows users to not have to see and potentially fret about whitespace on these lines when they copy/paste or edit these lines.

8. In the case though of:

```
var v1 = ""
    Start
<ten spaces>
    End
    ""
```

The 'indentation whitespace' will still be nine spaces. Here though, we will remove as much of the 'indentation whitespace' as possible, and the 'blank' `raw_content` will contribute a single space to the final content. This allows for cases where the content does need whitespace on these lines that should be preserved.

9. The following is technically not legal:

```
var v1 = ""  
      ""
```

This is because the start of the raw string must have a `new_line` (which it does) but the end must have a `new_line` as well (which it does not). The minimal legal `raw_string_literal` is:

```
var v1 = ""  
      ""
```

However, this string is decidedly uninteresting as it is equivalent to `""`.

Indentation examples

The 'indentation whitespace' algorithm can be visualized on several inputs like so:

Example 1 - Standard case

```
var xml = ""  
    <element attr="content">  
        <body>  
        </body>  
    </element>  
    "";
```

is interpreted as

```
var xml = ""  
    |<element attr="content">  
    | <body>  
    | </body>  
    |</element>  
    "";
```

Example 2 - End delimiter on same line as content.

```
var xml = ""
    <element attr="content">
        <body>
        </body>
    </element>"";
```

This is illegal. The last content line must end with a `new_line`.

Example 3 - End delimiter before start delimiter

```
var xml = ""
    <element attr="content">
        <body>
        </body>
    </element>
"";
```

is interpreted as

```
var xml = ""
|         <element attr="content">
|         <body>
|         </body>
|         </element>
"";
```

Example 4 - End delimiter after start delimiter

```
var xml = ""
    <element attr="content">
        <body>
        </body>
    </element>
    "";
```

This is illegal. The lines of content must start with the 'indentation whitespace'

Example 5 - Empty blank line

```
var xml = ""
  <element attr="content">
    <body>
    </body>

  </element>
  "";
```

is interpreted as

```
var xml = ""
  |<element attr="content">
  | <body>
  | </body>
  |
  |</element>
  "";
```

Example 5 - Blank line with less whitespace than prefix (dots represent spaces)

```
var xml = ""
  <element attr="content">
    <body>
    </body>
  ....
  </element>
  "";
```

is interpreted as

```
var xml = ""
  |<element attr="content">
  | <body>
  | </body>
  |
  |</element>
  "";
```

Example 5 - Blank line with more whitespace than prefix (dots represent spaces)

```
var xml = ""
    <element attr="content">
        <body>
        </body>
.....
    </element>
    "";
```

is interpreted as

```
var xml = ""
|<element attr="content">
| <body>
| </body>
|....
|</element>
|"";
```

Detailed design (interpolation case)

Interpolations in normal interpolated strings (e.g. `$"..."`) are supported today through the use of the `{` character to start an `interpolation` and the use of an `{{` escape-sequence to insert an actual open brace character. Using this same mechanism would violate goals '1' and '2' of this proposal. Languages that have `{` as a core character (examples being JavaScript, JSON, Regex, and even embedded C#) would now need escaping, undoing the purpose of raw string literals.

To support interpolations we introduce them in a different fashion than normal `$"` interpolated strings. Specifically, an `interpolated_raw_string_literal` will start with some number of `$` characters. The count of these indicates how many `{` (and `}`) characters are needed in the content of the literal to delimit the `interpolation`. Importantly, there continues to be no escaping mechanism for curly braces. Rather, just as with quotes (`"`) the literal itself can always ensure it specifies delimiters for the interpolations that are certain to not collide with any of the rest of the content of the string. For example a JSON literal containing interpolation holes can be written like so:

c#

```
var v1 = $$""
    {
        "orders":
        [
            { "number": {{order_number}} }
        ]
    }
    ""
```

Here, the `{{...}}` matches the requisite count of two braces specified by the `$$` delimiter prefix. In the case of a single `$` that means the interpolation is specified just as `{...}` as in normal interpolated string literals. Importantly, this means that an interpolated literal with `N` `$` characters can have a sequence of `2*N-1` braces (of the same type in a row). The last `N` braces will start (or end) an interpolation, and the remaining `N-1` braces will just be content. For example:

c#

```
var v1 = $$""X{{{1+1}}}Z"";
```

In this case the inner two `{{` and `}}` braces belong to the interpolation, and the outer singular braces are just content. So the above string is equivalent to the content `X{2}Z`. Having `2*N` (or more) braces is always an error. To have longer sequences of braces as content, the number of `$` characters must be increased accordingly.

Interpolated raw string literals are defined as:

```
interpolated_raw_string_literal
    : single_line_interpolated_raw_string_literal
    | multi_line_interpolated_raw_string_literal
    ;

interpolated_raw_string_start
    : $
    | $$
    | $$$
    | etc.
    ;

interpolated_raw_string_literal_delimiter
    : interpolated_raw_string_start raw_string_literal_delimiter
    ;
```

```

single_line_interpolated_raw_string_literal
    : interpolated_raw_string_literal_delimiter interpolated_raw_content
raw_string_literal_delimiter
    ;

multi_line_interpolated_raw_string_literal
    : interpolated_raw_string_literal_delimiter whitespace* new_line
(interpolated_raw_content | new_line)* new_line whitespace*
raw_string_literal_delimiter
    ;

interpolated_raw_content
    : (not_new_line | raw_interpolation)+
    ;

raw_interpolation
    : raw_interpolation_start interpolation raw_interpolation_end
    ;

raw_interpolation_start
    : {
    | {{
    | {{{
    | etc.
    ;

raw_interpolation_end
    : }
    | }}
    | }}}
    | etc.
    ;

```

The above is similar to the definition of `raw_string_literal` but with some important differences. A `interpolated_raw_string_literal` should be interpreted as:

1. It starts with at least one dollar sign (but no upper bound) and then three quotes (also with no upper bound).
2. It then continues with content on the same line as the starting quotes. This content on the same line can be blank, or non-blank. 'blank' is synonymous with 'entirely whitespace'.
3. If the content on that same line is non-blank no further content can follow. In other words the literal is required to end with the same number of quotes on that same line.
4. If the contents on the same line is blank, then the literal can continue with a `new_line` and some number of subsequent content lines and `new_lines`.
 - A content line is any text except a `new_line`.

- A content line can contain multiple `raw_interpolation` occurrences at any position. The `raw_interpolation` must start with an equal number of open braces (`{`) as the number of dollar signs at the start of the literal.
- If 'indentation whitespace' is not-empty, a `raw_interpolation` cannot immediately follow a `new_line`.
- The `raw_interpolation` will following the normal rules specified at [§11.7.3](#). Any `raw_interpolation` must end with the same number of close braces (`}`) as dollar signs and open braces.
- Any `interpolation` can itself contain new-lines within in the same manner as an `interpolation` in a normal `verbatim_string_literal` (`@"`). It then ends with a `new_line` some number (possibly zero) of `whitespace` and the same number of quotes that the literal started with.

Computation of the interpolated string value follows the same rules as a normal `raw_string_literal` except updated to handle lines containing `raw_interpolation`s. Building the string value happens in the same fashion, just with the interpolation holes replaced with whatever values those expressions produce at runtime. If the `interpolated_raw_string_literal` is converted to a `FormattableString` then the values of the interpolations are passed in their respective order to the `arguments` array to `FormattableString.Create`. The rest of the content of the `interpolated_raw_string_literal` after the 'indentation whitespace' has been stripped from all lines will be used to generate `format` string passed to `FormattableString.Create`, except with appropriately numbered `{N}` contents in each location where a `raw_interpolation` occurred (or `{N,constant}` in the case if its `interpolation` is of the form `expression ', ' constant_expression`).

There is an ambiguity in the above specification. Specifically when a section of `{` in text and `}` of an interpolation abut. For example:

```
var v1 = $$"""
    {{{order_number}}}
```

This could be interpreted as: `{{ {order_number} }}` or `{ {{order_number}} }`. However, as the former is illegal (no C# expression could start with `{`) it would be pointless to interpret that way. So we interpret in the latter fashion, where the innermost `{` and `}` braces form the interpolation, and any outermost ones form the text. In the future this might be an issue if the language ever supports any expressions that are surrounded by

braces. However, in that case, the recommendation would be to write such a case like so: `{{({some_new_expression_form})}}`. Here, parentheses would help designate the expression portion from the rest of the literal/interpolation. This has precedence already with how ternary conditional expressions need to be wrapped to not conflict with the formatting/alignment specifier of an interpolation (e.g. `{(x ? y : z)}`).

Examples: (upcoming)

Drawbacks

Raw string literals add more complexity to the language. We already have many string literal forms already for numerous purposes. `"""` strings, `@"""` strings, and `$"""` strings already have a lot of power and flexibility. But they all lack a way to provide raw contents that never need escaping.

The above rules do not support the case of 4.a:

4. ...

- Optionally, with extra complexity, we could refine this to state that: For all strings that do not themselves contain a `new_line` (but can start or end with a quote `"` character), it should be possible to represent the string literal itself on a single line.

That's because we have no means to know that a starting or ending quote (`"`) should belong to the contents and not the delimiter itself. If this is an important scenario we want to support though, we can add a parallel `'''` construct to go along with the `"""` form. With that parallel construct, a single line string that start and ends with `"` can be written easily as `'''This string starts and ends with quotes'''` along with the parallel construct `''''This string starts and ends with apostrophes''''`. This may also be desirable to support to help visually separate out quote characters, which may help when embedding languages that primarily use one quote character much more than then other.

Alternatives

<https://github.com/dotnet/csharpplang/discussions/89> [↗](#) covers many options here. Alternatives are numerous, but i feel stray too far into complexity and poor ergonomics. This approach opts for simplicity where you just keep increasing the start/end quote length until there is no concern about a conflict with the string contents. It also allows

the code you write to look well indented, while still producing a dedented literal that is what most code wants.

One of the most interesting potential variations though is the use of ``` (or `````) fences for these raw string literals. This would have several benefits:

1. It would avoid all the issues with strings starting or ending with quotes.
2. It would look familiar to markdown. Though that in itself is potentially not a good thing as users might expect markdown interpretation.
3. A raw string literal would only have to start and end with a single character in most cases, and would only need multiple in the much rarer case of contents that contain back-ticks themselves.
4. It would feel natural to extend this in the future with ````xml`, again akin to markdown. Though, of course, that is also true of the `"""` form.

Overall though, the net benefit here seems small. In keeping with C# history, I think `"` should continue to be the `string literal` delimiter, just as it is for `@""` and `$""`.

Design meetings

~~Open issues to discuss~~ Resolved issues:

- [x] should we have a single line form? We technically could do without it. But it would mean simple strings not containing a newline would always take at least three lines. I think we should. It's very heavyweight to force single line constructs to be three lines just to avoid escaping.

Design decision: Yes, we will have a single line form.

- [x] should we require that multiline *must* start with a newline? I think we should. It also gives us the ability to support things like `"""xml` in the future.

Design decision: Yes, we will require that multiline *must* start with a newline

- [x] should the automatic dedenting be done at all? I think we should. It makes code look so much more pleasant.

Design decision: Yes, automatic dedenting will be done.

- [x] should we restrict common-whitespace from mixing whitespace types? I don't think we should. Indeed, there is a common indentation strategy called "tab for indentation, space for alignment". It would be very natural to use this to align the

end delimiter with the start delimiter in a case where the start delimiter doesn't start on a tab stop.

Design decision: We will not have any restrictions on mixing whitespace.

- [x] should we use something else for the fences? ``` would match markdown syntax, and would mean we didn't need to always start these strings with three quotes. Just one would suffice for the common case.

Design decision: We will use `"""`

- [x] should we have a requirement that the delimiter have more quotes than the longest sequence of quotes in the string value? Technically it's not required. for example:

```
var v = """
    contents""""
    """
```

This is a string with `"""` as the delimiter. Several community members have stated this is confusing and we should require in a case like this that the delimiter always have more characters. That would then be:

```
var v = """"""
    contents""""
    """"
```

Design decision: Yes, the delimiter must be longer than any sequence of quotes in the string itself.

Allow new-lines in all interpolations

Article • 2022-09-27 • 2 minutes to read

- [x] Proposed
- [x] Implementation: <https://github.com/dotnet/roslyn/pull/56853> ↗
- [x] Specification: this file.

Summary

The language today non-verbatim and verbatim interpolated strings (`$""` and `$@"` respectively). The primary *sensible* difference for these is that a non-verbatim interpolated string works like a normal string and cannot contain newlines in its text segments, and must instead use escapes (like `\r\n`). Conversely, a verbatim interpolated string can contain newlines in its text segments (like a verbatim string), and doesn't escape newlines or other character (except for `"` to escape a quote itself).

This is all reasonable and will not change with this proposal.

What is unreasonable today is that we extend the restriction on 'no newlines' in a non-verbatim interpolated string *beyond* its text segments into the *interpolations* themselves. This means, for example, that you cannot write the following:

```
c#  
  
var v = $"Count is\t: { this.Is.A.Really(long(expr))  
                .That.I.Should(  
                    be + able)[  
                        to.Wrap() ] }.";
```

Ultimately, the 'interpolation must be on a single line itself' rule is just a restriction of the current implementation. That restriction really isn't necessary, and can be annoying, and would be fairly trivial to remove (see work <https://github.com/dotnet/roslyn/pull/54875> ↗ to show how). In the end, all it does is force the dev to place things on a single line, or force them into a verbatim interpolated string (both of which may be unpalatable).

The interpolation expressions themselves are not text, and shouldn't be beholden to any escaping/newline rules therein.

Utf8 Strings Literals

Article • 2022-09-27 • 17 minutes to read

Summary

This proposal adds the ability to write UTF8 string literals in C# and have them automatically encoded into their UTF-8 `byte` representation.

Motivation

UTF8 is the language of the web and its use is necessary in significant portions of the .NET stack. While much of data comes in the form of `byte[]` off the network stack there is still significant uses of constants in the code. For example networking stack has to commonly write constants like `"HTTP/1.0\r\n"`, `" AUTH"` or `"Content-Length: "`.

Today there is no efficient syntax for doing this as C# represents all strings using UTF16 encoding. That means developers have to choose between the convenience of encoding at runtime which incurs overhead, including the time spent at startup actually performing the encoding operation (and allocations if targeting a type that doesn't actually require them), or manually translating the bytes and storing in a `byte[]`.

c#

```
// Efficient but verbose and error prone
static ReadOnlySpan<byte> AuthWithTrailingSpace => new byte[] { 0x41, 0x55,
0x54, 0x48, 0x20 };
WriteBytes(AuthWithTrailingSpace);

// Incurs allocation and startup costs performing an encoding that could
have been done at compile-time
static readonly byte[] s_authWithTrailingSpace =
Encoding.UTF8.GetBytes("AUTH ");
WriteBytes(s_authWithTrailingSpace);

// Simplest / most convenient but terribly inefficient
WriteBytes(Encoding.UTF8.GetBytes("AUTH "));
```

This trade off is a pain point that comes up frequently for our partners in the runtime, ASP.NET and Azure. Often times it causes them to leave performance on the table because they don't want to go through the hassle of writing out the `byte[]` encoding by hand.

To fix this we will allow for UTF8 literals in the language and encode them into the UTF8 `byte[]` at compile time.

Detailed design

`u8` suffix on string literals

The language will provide the `u8` suffix on string literals to force the type to be UTF8. The suffix is case-insensitive, `U8` suffix will be supported and will have the same meaning as `u8` suffix.

When the `u8` suffix is used, the value of the literal is a `ReadOnlySpan<byte>` containing a UTF-8 byte representation of the string. A null terminator is placed beyond the last byte in memory (and outside the length of the `ReadOnlySpan<byte>`) in order to handle some interop scenarios where the call expects null terminated strings.

c#

```
string s1 = "hello"u8;           // Error
var s2 = "hello"u8;             // Okay and type is ReadOnlySpan<byte>
ReadOnlySpan<byte> s3 = "hello"u8; // Okay.
byte[] s4 = "hello"u8;          // Error - Cannot implicitly convert type
'System.ReadOnlySpan<byte>' to 'byte[]'.
byte[] s5 = "hello"u8.ToArray(); // Okay.
Span<byte> s6 = "hello"u8;       // Error - Cannot implicitly convert type
'System.ReadOnlySpan<byte>' to 'System.Span<byte>'.
```

Since the literals would be allocated as global constants, the lifetime of the resulting `ReadOnlySpan<byte>` would not prevent it from being returned or passed around to elsewhere. However, certain contexts, most notably within async functions, do not allow locals of ref struct types, so there would be a usage penalty in those situations, with a `ToArray()` call or similar being required.

A `u8` literal doesn't have a constant value. That is because `ReadOnlySpan<byte>` cannot be type of a constant today. If the definition of `const` is expanded in the future to consider `ReadOnlySpan<byte>`, then this value should also be considered a constant. Practically though this means a `u8` literal cannot be used as the default value of an optional parameter.

c#

```
// Error: The argument is not constant
void Write(ReadOnlySpan<byte> message = "missing"u8) { ... }
```

When the input text for the literal is a malformed UTF16 string, then the language will emit an error:

```
c#
```

```
var bytes = "hello \uD801\uD802"u8; // Error: the input string is not valid UTF16
```

Addition operator

A new bullet point will be added to [§11.9.5 Addition operator](#) as follows.

- UTF8 byte representation concatenation:

```
C#
```

```
ReadOnlySpan<byte> operator +(ReadOnlySpan<byte> x, ReadOnlySpan<byte> y);
```

This binary `+` operator performs byte sequences concatenation and is applicable if and only if both operands are semantically UTF8 byte representations. An operand is semantically a UTF8 byte representation when it is either a value of a `u8` literal, or a value produced by the UTF8 byte representation concatenation operator.

The result of the UTF8 byte representation concatenation is a `ReadOnlySpan<byte>` that consists of the bytes of the left operand followed by the bytes of the right operand. A null terminator is placed beyond the last byte in memory (and outside the length of the `ReadOnlySpan<byte>`) in order to handle some interop scenarios where the call expects null terminated strings.

Lowering

The language will lower the UTF8 encoded strings exactly as if the developer had typed the resulting `byte[]` literal in code. For example:

```
c#
```

```
ReadOnlySpan<byte> span = "hello"u8;
```

```
// Equivalent to
```

```
ReadOnlySpan<byte> span = new ReadOnlySpan<byte>(new byte[] { 0x68, 0x65, 0x6c, 0x6c, 0x66, 0x00 }).
```

```
Slice(0,5); // The `Slice` call will be
optimized away by the compiler.
```

That means all optimizations that apply to the `new byte[] { ... }` form will apply to utf8 literals as well. This means the call site will be allocation free as C# will optimize this be stored in the `.data` section of the PE file.

Multiple consecutive applications of UTF8 byte representation concatenation operators are collapsed into a single creation of `ReadOnlySpan<byte>` with byte array containing the final byte sequence.

```
c#
```

```
ReadOnlySpan<byte> span = "h"u8 + "e1"u8 + "lo"u8;

// Equivalent to

ReadOnlySpan<byte> span = new ReadOnlySpan<byte>(new byte[] { 0x68, 0x65,
0x6c, 0x6c, 0x6f, 0x00 }).
    Slice(0,5); // The `Slice` call will be
optimized away by the compiler.
```

Drawbacks

Relying on core APIs

The compiler implementation will use `UTF8Encoding` for both invalid string detection as well as translation to `byte[]`. The exact APIs will possibly depend on which target framework the compiler is using. But `UTF8Encoding` will be the workhorse of the implementation.

Historically the compiler has avoided using runtime APIs for literal processing. That is because it takes control of how constants are processed away from the language and into the runtime. Concretely it means items like bug fixes can change constant encoding and mean that the outcome of C# compilation depends on which runtime the compiler is executing on.

This is not a hypothetical problem. Early versions of Roslyn used `double.Parse` to handle floating point constant parsing. That caused a number of problems. First it meant that some floating point values had different representations between the native compiler and Roslyn. Second as .NET core evolved and fixed long standing bugs in the `double.Parse` code it meant that the meaning of those constants changed in the

language depending on what runtime the compiler executed on. As a result the compiler ended up writing it's own version of floating point parsing code and removing the dependency on `double.Parse`.

This scenario was discussed with the runtime team and we do not feel it has the same problems we've hit before. The UTF8 parsing is stable across runtimes and there are no known issues in this area that are areas for future compat concerns. If one does come up we can re-evaluate the strategy.

Alternatives

Target type only

The design could rely on target typing only and remove the `u8` suffix on `string` literals. In the majority of cases today the `string` literal is being assigned directly to a `ReadOnlySpan<byte>` hence it's unnecessary.

```
c#  
  
ReadOnlySpan<byte> span = "Hello World;
```

The `u8` suffix exists primarily to support two scenarios: `var` and overload resolution. For the latter consider the following use case:

```
c#  
  
void Write(ReadOnlySpan<byte> span) { ... }  
void Write(string s) {  
    var bytes = Encoding.UTF8.GetBytes(s);  
    Write(bytes.AsSpan());  
}
```

Given the implementation it is better to call `Write(ReadOnlySpan<byte>)` and the `u8` suffix makes this convenient: `Write("hello"u8)`. Lacking that developers need to resort to awkward casting `Write((ReadOnlySpan<byte>)"hello")`.

Still this is a convenience item, the feature can exist without it and it is non-breaking to add it at a later time.

Wait for Utf8String type

```
const string text = "hello \uD801\uD802";
byte[] bytes = text; // Error: the input string is not valid UTF16
```

The predominant usage of this feature is expected to be with literals but it will work with any `string` constant value. A conversion from a `string` constant with `null` value will be supported as well. The result of the conversion will be `default` value of the target type.

c#

```
const string data = "dog"
ReadOnlySpan<byte> span = data; // new byte[] { 0x64, 0x66, 0x67 }
```

In the case of any constant operation on strings, such as `+`, the encoding to UTF8 will occur on the final `string` vs. happening for the individual parts and then concatenating the results. This ordering is important to consider because it can impact whether or not the conversion succeeds.

c#

```
const string first = "\uD83D"; // high surrogate
const string second = "\uDE00"; // low surrogate
ReadOnlySpan<byte> span = first + second;
```

The two parts here are invalid on their own as they are incomplete portions of a surrogate pair. Individually there is no correct translation to UTF8 but together they form a complete surrogate pair that can be successfully translated to UTF8.

The *string_constant_to_UTF8_byte_representation_conversion* is not allowed in Linq Expression Trees.

While the inputs to these conversions are constants and the data is fully encoded at compile time, the conversion is **not** considered constant by the language. That is because arrays are not constant today. If the definition of `const` is expanded in the future to consider arrays then these conversions should also be considered. Practically though this means a result of these conversions cannot be used as the default value of an optional parameter.

c#

```
// Error: The argument is not constant
void Write(ReadOnlySpan<byte> message = "missing") { ... }
```

Once implemented string literals will have the same problem that other literals have in the language: what type they represent depends on how they are used. C# provides a literal suffix to disambiguate the meaning for other literals. For example developers can write `3.14f` to force the value to be a `float` or `1L` to force the value to be a `long`.

Unresolved questions

(Resolved) Conversions between a `string` constant with `null` value and `byte` sequences

Whether this conversion is supported and, if so, how it is performed is not specified.

Proposal:

Allow implicit conversions from a `string` constant with `null` value to `byte[]`, `Span<byte>`, and `ReadOnlySpan<byte>`. The result of the conversion is `default` value of the target type.

Resolution:

The proposal is approved -

<https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01-26.md#conversions-from-null-literals>.

(Resolved) Where does `string_constant_to_UTF8_byte_representation_conversion` belong?

Is `string_constant_to_UTF8_byte_representation_conversion` a bullet point in the implicit conversions §10.2 section on its own, or is it part of §10.2.11, or does it belong to some other existing implicit conversions group?

Proposal:

It is a new bullet point in implicit conversions §10.2, similar to "Implicit interpolated string conversions" or "Method group conversions". It doesn't feel like it belongs to "Implicit constant expression conversions" because, even though the source is a constant expression, the result is never a constant expression. Also, "Implicit constant expression conversions" are considered to be "Standard implicit conversions" §10.4.2, which is likely to lead to non-trivial behavior changes involving user-defined conversions.

Resolution:

We will introduce a new conversion kind for string constant to UTF-8 bytes - <https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01-26.md#conversion-kinds> 

(Resolved) Is *string_constant_to_UTF8_byte_representation_conversion* a standard conversion

In addition to "pure" Standard Conversions (the standard conversions are those pre-defined conversions that can occur as part of a user-defined conversion), compiler also treats some predefined conversions as "somewhat" standard. For example, an implicit interpolated string conversion can occur as part of a user-defined conversion if there is an explicit cast to the target type in code. As if it is a Standard Explicit Conversion, even though it is an implicit conversion not explicitly included into the set of standard implicit or explicit conversions. For example:

```
C#  
  
class C  
{  
    static void Main()  
    {  
        C1 x = $"hello"; // error CS0266: Cannot implicitly convert type  
        'string' to 'C1'. An explicit conversion exists (are you missing a cast?)  
        var y = (C1)$"dog"; // works  
    }  
}  
  
class C1  
{  
    public static implicit operator C1(System.FormattableString x) => new  
    C1();  
}
```

Proposal:

The new conversion is not a standard conversion. This will avoid non-trivial behavior changes involving user-defined conversions. For example, we won't need to worry about user-defined conversions under implicit tuple literal conversions, etc.

Resolution:

Not a standard conversion, for now - <https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01->

(Resolved) Linq Expression Tree conversion

Should `string_constant_to_UTF8_byte_representation_conversion` be allowed in context of a Linq Expression Tree conversion? We can disallow it for now, or we could simply include the "lowered" form into the tree. For example:

```
C#  
  
Expression<Func<byte[]>> x = () => "hello";           // () => new [] {104,  
101, 108, 108, 111}  
Expression<FuncSpanOfByte> y = () => "dog";         // () => new  
Span`1(new [] {100, 111, 103})  
Expression<FuncReadOnlySpanOfByte> z = () => "cat"; // () => new  
ReadOnlySpan`1(new [] {99, 97, 116})
```

What about string literals with `u8` suffix? We could surface those as byte array creations:

```
C#  
  
Expression<Func<byte[]>> x = () => "hello"u8;       // () => new []  
{104, 101, 108, 108, 111}
```

Resolution:

Disallow in Linq Expression Trees -

<https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01-26.md#expression-tree-representation>.

(Resolved) The natural type of a string literal with `u8` suffix

The "Detailed design" section says: "The natural type though will be `ReadOnlySpan<byte>`." At the same time: "When the `u8` suffix is used the literal can still be converted to any of the allowed types: `byte[]`, `Span<byte>` or `ReadOnlySpan<byte>`."

There are several disadvantages with this approach:

- `ReadOnlySpan<byte>` is not available on desktop framework;
- There are no existing conversions from `ReadOnlySpan<byte>` to `byte[]` or `Span<byte>`. In order to support them we will likely need to treat the literals as

target typed. Both the language rules and implementation will become more complicated.

Proposal:

The natural type will be `byte[]`. It is readily available on all frameworks. BTW, at runtime we will always be starting with creating a byte array, even with the original proposal. We also don't need any special conversion rules to support conversions to `Span<byte>` and `ReadOnlySpan<byte>`. There are already implicit user-defined conversions from `byte[]` to `Span<byte>` and `ReadOnlySpan<byte>`. There is even implicit user-defined conversion to `ReadOnlyMemory<byte>` (see the "Depth of the conversion" question below). There is a disadvantage, language doesn't allow chaining user-defined conversions. So, the following code will not compile:

```
C#  
  
using System;  
class C  
{  
    static void Main()  
    {  
        var y = (C2)"dog"u8; // error CS0030: Cannot convert type 'byte[]'  
to 'C2'  
        var z = (C3)"cat"u8; // error CS0030: Cannot convert type 'byte[]'  
to 'C3'  
    }  
}  
  
class C2  
{  
    public static implicit operator C2(Span<byte> x) => new C2();  
}  
  
class C3  
{  
    public static explicit operator C3(ReadOnlySpan<byte> x) => new C3();  
}
```

However, as with any user-defined conversion, an explicit cast can be used to make one user-defined conversion a part of another user-defined conversion.

It feels like all motivating scenarios are going to be addressed with `byte[]` as the natural type, but the language rules and implementation will be significantly simpler.

Resolution:

The proposal is approved -

<https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01->

[26.md#natural-type-of-u8-literals](#). We will likely want to have a deeper debate about whether `u8` string literals should have a type of a mutable array, but we don't think that debate is necessary for now.

(Resolved) Depth of the conversion

Will it also work anywhere that a `byte[]` could work? Consider:

```
c#
```

```
static readonly ReadOnlyMemory<byte> s_data1 = "Data"u8;  
static readonly ReadOnlyMemory<byte> s_data2 = "Data";
```

The first example likely should work because of the natural type that comes from `u8`.

The second example is hard to make work because it requires conversions in both directions. That is unless we add `ReadOnlyMemory<byte>` as one of the allowed conversion types.

Proposal:

Don't do anything special.

Resolution:

No new conversion targets added for now

<https://github.com/dotnet/csharpplang/blob/main/meetings/2022/LDM-2022-01-26.md#conversion-depth>.

(Resolved) Overload resolution breaks

The following API would become ambiguous:

```
c#
```

```
M("");  
static void M1(ReadOnlySpan<char> charArray) => ...;  
static void M1(byte[] byteArray) => ...;
```

What should we do to address this?

Proposal:

Similar to <https://github.com/dotnet/csharp-lang/blob/main/proposals/csharp-10.0/lambda-improvements.md#overload-resolution>, Better function member (§11.6.4.3) is updated to prefer members where none of the conversions involved require converting `string` constants to UTF8 `byte` sequences.

Better function member

... Given an argument list `A` with a set of argument expressions `{E1, E2, ..., En}` and two applicable function members `Mp` and `Mq` with parameter types `{P1, P2, ..., Pn}` and `{Q1, Q2, ..., Qn}`, `Mp` is defined to be a **better function member** than `Mq` if

1. for each argument, the implicit conversion from `Ex` to `Px` is not a *string_constant_to_UTF8_byte_representation_conversion*, and for at least one argument, the implicit conversion from `Ex` to `Qx` is a *string_constant_to_UTF8_byte_representation_conversion*, or
2. for each argument, the implicit conversion from `Ex` to `Px` is not a *function_type_conversion*, and
 - `Mp` is a non-generic method or `Mp` is a generic method with type parameters `{X1, X2, ..., Xp}` and for each type parameter `xi` the type argument is inferred from an expression or from a type other than a *function_type*, and
 - for at least one argument, the implicit conversion from `Ex` to `Qx` is a *function_type_conversion*, or `Mq` is a generic method with type parameters `{Y1, Y2, ..., Yq}` and for at least one type parameter `yi` the type argument is inferred from a *function_type*, or
3. for each argument, the implicit conversion from `Ex` to `Qx` is not better than the implicit conversion from `Ex` to `Px`, and for at least one argument, the conversion from `Ex` to `Px` is better than the conversion from `Ex` to `Qx`.

Note that the addition of this rule is not going to cover scenarios with instance methods becoming applicable and "shadowing" extension methods. For example:

```
C#  
  
using System;  
  
class Program  
{  
    static void Main()  
}
```

```

    {
        var p = new Program();
        Console.WriteLine(p.M(""));
    }

    public string M(byte[] b) => "byte[]";
}

static class E
{
    public static string M(this object o, string s) => "string";
}

```

Behavior of this code will silently change from printing "string" to printing "byte[]".

Are we Ok with this behavior change? Should it be documented as a breaking change?

Note that there is no proposal to make *string_constant_to_UTF8_byte_representation_conversion* unavailable when C#10 language version is targeted. In that case, the example above becomes an error rather than returns to C#10 behavior. This follows a general principle that target language version doesn't affect semantics of the language.

Are we Ok with this behavior? Should it be documented as a breaking change?

The new rule also is not going to prevent breaks involving tuple literal conversions. For example,

```

C#

class C
{
    static void Main()
    {
        System.Console.Write(Test(("s", 1)));
    }

    static string Test((object, int) a) => "object";
    static string Test((byte[], int) a) => "array";
}

```

is going to silently print "array" instead of "object".

Are we Ok with this behavior? Should it be documented as a breaking change? Perhaps we could complicate the new rule to dig into the tuple literal conversions.

Resolution:

The prototype will not adjust any rules here, so we can hopefully see what breaks in practice - <https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01-26.md#breaking-changes> .

(Resolved) Should `u8` suffix be case-insensitive?

Proposal:

Support `u8` suffix as well for consistency with numeric suffixes.

Resolution:

Approved - <https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-01-26.md#suffix-case-sensitivity> .

Examples today

Pattern match `Span<char>` on a constant string

Article • 2022-09-27 • 3 minutes to read

Summary

Permit pattern matching a `Span<char>` and a `ReadOnlySpan<char>` on a constant string.

Motivation

For performance, usage of `Span<char>` and `ReadOnlySpan<char>` is preferred over string in many scenarios. The framework has added many new APIs to allow you to use `ReadOnlySpan<char>` in place of a `string`.

A common operation on strings is to use a switch to test if it is a particular value, and the compiler optimizes such a switch. However there is currently no way to do the same on a `ReadOnlySpan<char>` efficiently, other than implementing the switch and the optimization manually.

In order to encourage adoption of `ReadOnlySpan<char>` we allow pattern matching a `ReadOnlySpan<char>`, on a constant `string`, thus also allowing it to be used in a switch.

C#

```
static bool Is123(ReadOnlySpan<char> s)
{
    return s is "123";
}

static bool IsABC(Span<char> s)
{
    return s switch { "ABC" => true, _ => false };
}
```

Detailed design

We alter the `spec` for constant patterns as follows (the proposed addition is shown in bold):

A constant pattern tests the value of an expression against a constant value. The constant may be any constant expression, such as a literal, the name of a declared `const` variable, or an enumeration constant, or a `typeof` expression etc.

If both `e` and `c` are of integral types, the pattern is considered matched if the result of the expression `e == c` is `true`.

If `e` is of type `System.Span<char>` or `System.ReadOnlySpan<char>`, and `c` is a constant string, and `c` does not have a constant value of `null`, then the pattern is considered matching if `System.MemoryExtensions.SequenceEqual<char>(e, System.MemoryExtensions.AsSpan(c))` returns `true`.

Otherwise the pattern is considered matching if `object.Equals(e, c)` returns `true`. In this case it is a compile-time error if the static type of `e` is not *pattern compatible* with the type of the constant.

Well-known members

`System.Span<T>` and `System.ReadOnlySpan<T>` are matched by name, must be `ref structs`, and can be defined outside `corlib`.

`System.MemoryExtensions` is matched by name and can be defined outside `corlib`.

The signature of `System.MemoryExtensions.SequenceEqual` overloads must match:

- `public static bool SequenceEqual<T>(System.Span<T>, System.ReadOnlySpan<T>)`
- `public static bool SequenceEqual<T>(System.ReadOnlySpan<T>, System.ReadOnlySpan<T>)`

The signature of `System.MemoryExtensions.AsSpan` must match:

- `public static System.ReadOnlySpan<char> AsSpan(string)`

Methods with optional parameters are excluded from consideration.

Drawbacks

None

Alternatives

None

Unresolved questions

1. Should matching be defined independently from

`MemoryExtensions.SequenceEqual()` etc.?

... the pattern is considered matching if `e.Length == c.Length` and `e[i] == c[i]` for all characters in `e`.

Recommendation: Define in terms of `MemoryExtensions.SequenceEqual()` for performance. If `MemoryExtensions` is missing, report compile error.

2. Should matching against `(string)null` be allowed?

If so, should `(string)null` subsume `""` since `MemoryExtensions.AsSpan(null) == MemoryExtensions.AsSpan("")`?

```
C#  
  
static bool IsEmpty(ReadOnlySpan<char> span)  
{  
    return span switch  
    {  
        (string)null => true, // ok?  
        "" => true, // error: unreachable?  
        _ => false,  
    };  
}
```

Recommendation: Constant pattern `(string)null` should be reported as an error.

3. Should the constant pattern match include a runtime type test of the expression value for `Span<char>` or `ReadOnlySpan<char>`?

```
C#  
  
static bool Is123<T>(Span<T> s)  
{  
    return s is "123"; // test for Span<char>?  
}  
  
static bool IsABC<T>(Span<T> s)  
{  
    return s is Span<char> and "ABC"; // ok?  
}  
  
static bool IsEmptyString<T>(T t) where T : ref struct  
{
```

```
return t is ""; // test for ReadOnlySpan<char>, Span<char>, string?
}
```

Recommendation: No implicit runtime type test for constant pattern. (`IsABC<T>()` example is allowed because the type test is explicit.)

4. Should subsumption consider constant string patterns, list patterns, and `Length` property pattern?

```
C#
static int ToNum(ReadOnlySpan<char> s)
{
    return s switch
    {
        { Length: 0 } => 0,
        "" => 1,           // error: unreachable?
        ['A', ..] => 2,
        "ABC" => 3,       // error: unreachable?
        _ => 4,
    };
}
```

Recommendation: Same subsumption behavior as used when the expression value is `string`. (Does that mean no subsumption between constant strings, list patterns, and `Length`, other than treating `[..]` as matching any?)

List patterns

Article • 2022-09-27 • 4 minutes to read

Summary

Lets you to match an array or a list with a sequence of patterns e.g. `array is [1, 2, 3]` will match an integer array of the length three with 1, 2, 3 as its elements, respectively.

Detailed design

The pattern syntax is modified as follow:

```
antlr

list_pattern_clause
: '[' (pattern (',' pattern)* ','?)? ']'
;

list_pattern
: list_pattern_clause simple_designation?
;

slice_pattern
: '..' pattern?
;

primary_pattern
: list_pattern
| slice_pattern
| // all of the pattern forms previously defined
;
```

There are two new patterns:

- The *list_pattern* is used to match elements.
- A *slice_pattern* is only permitted once and only directly in a *list_pattern_clause* and discards **zero or more** elements.

Pattern compatibility

A *list_pattern* is compatible with any type that is *countable* as well as *indexable* — it has an accessible indexer that takes an `Index` as an argument or otherwise an accessible

indexer with a single `int` parameter. If both indexers are present, the former is preferred.

A *slice_pattern* with a subpattern is compatible with any type that is *countable* as well as *sliceable* — it has an accessible indexer that takes a `Range` as an argument or otherwise an accessible `slice` method with two `int` parameters. If both are present, the former is preferred.

A *slice_pattern* without a subpattern is compatible with any type that is compatible with a *list_pattern*.

This set of rules is derived from the [range indexer pattern](#).

Subsumption checking

Subsumption checking works just like [positional patterns with ITuple](#) - corresponding subpatterns are matched by position plus an additional node for testing length.

For example, the following code produces an error because both patterns yield the same DAG:

```
C#
```

```
case [_, .., 1]: // expr.Length is >= 2 && expr[^1] is 1
case [.., _, 1]: // expr.Length is >= 2 && expr[^1] is 1
```

Unlike:

```
C#
```

```
case [_, 1, ..]: // expr.Length is >= 2 && expr[1] is 1
case [.., 1, _]: // expr.Length is >= 2 && expr[^2] is 1
```

The order in which subpatterns are matched at runtime is unspecified, and a failed match may not attempt to match all subpatterns.

Given a specific length, it's possible that two subpatterns refer to the same element, in which case a test for this value is inserted into the decision DAG.

- For instance, `[_, >0, ..]` or `[.., <=0, _]` becomes `length >= 2 && ([1] > 0 || length == 3 || [^2] <= 0)` where the length value of 3 implies the other test.
- Conversely, `[_, >0, ..]` and `[.., <=0, _]` becomes `length >= 2 && [1] > 0 && length != 3 && [^2] <= 0` where the length value of 3 disallows the other test.

As a result, an error is produced for something like `case [.., p]: case [p]:` because at runtime, we're matching the same element in the second case.

If a slice subpattern matches a list or a length value, subpatterns are treated as if they were a direct subpattern of the containing list. For instance, `[..[1, 2, 3]]` subsumes a pattern of the form `[1, 2, 3]`.

The following assumptions are made on the members being used:

- The property that makes the type *countable* is assumed to always return a non-negative value, if and only if the type is *indexable*. For instance, the pattern `{ Length: -1 }` can never match an array.
- The member that makes the type *sliceable* is assumed to be well-behaved, that is, the return value is never null and that it is a proper subslice of the containing list.

The behavior of a pattern-matching operation is undefined if any of the above assumptions doesn't hold.

Lowering

A pattern of the form `expr is [1, 2, 3]` is equivalent to the following code:

```
C#  
  
expr.Length is 3  
&& expr[new Index(0, fromEnd: false)] is 1  
&& expr[new Index(1, fromEnd: false)] is 2  
&& expr[new Index(2, fromEnd: false)] is 3
```

A *slice_pattern* acts like a proper discard i.e. no tests will be emitted for such pattern, rather it only affects other nodes, namely the length and indexer. For instance, a pattern of the form `expr is [1, .. var s, 3]` is equivalent to the following code (if compatible via explicit `Index` and `Range` support):

```
C#  
  
expr.Length is >= 2  
&& expr[new Index(0, fromEnd: false)] is 1  
&& expr[new Range(new Index(1, fromEnd: false), new Index(1, fromEnd:  
true))] is var s  
&& expr[new Index(1, fromEnd: true)] is 3
```

The *input type* for the *slice_pattern* is the return type of the underlying `this[Range]` or `slice` method with two exceptions: For `string` and arrays, `string.Substring` and

`RuntimeHelpers.GetSubArray` will be used, respectively.

Unresolved questions

1. Should we support multi-dimensional arrays? (answer [LDM 2021-05-26]: Not supported. If we want to make a general MD-array focused release, we would want to revisit all the areas they're currently lacking, not just list patterns.)
2. Should we accept a general *pattern* following `..` in a *slice_pattern*? (answer [LDM 2021-05-26]: Yes, any pattern is allowed after a slice.)
3. By this definition, the pattern `[..]` tests for `expr.Length >= 0`. Should we omit such test, assuming `Length` is always non-negative? (answer [LDM 2021-05-26]: `[..]` will not emit a Length check)

Required Members

Article • 2023-01-06 • 19 minutes to read

Summary

This proposal adds a way of specifying that a property or field is required to be set during object initialization, forcing the instance creator to provide an initial value for the member in an object initializer at the creation site.

Motivation

Object hierarchies today require a lot of boilerplate to carry data across all levels of the hierarchy. Let's look at a simple hierarchy involving a `Person` as might be defined in C# 8:

C#

```
class Person
{
    public string FirstName { get; }
    public string MiddleName { get; }
    public string LastName { get; }

    public Person(string firstName, string lastName, string? middleName =
null)
    {
        FirstName = firstName;
        LastName = lastName;
        MiddleName = middleName ?? string.Empty;
    }
}

class Student : Person
{
    public int ID { get; }
    public Student(int id, string firstName, string lastName, string?
middleName = null)
        : base(firstName, lastName, middleName)
    {
        ID = id;
    }
}
```

There's lots of repetition going on here:

1. At the root of the hierarchy, the type of each property had to be repeated twice, and the name had to be repeated four times.
2. At the derived level, the type of each inherited property had to be repeated once, and the name had to be repeated twice.

This is a simple hierarchy with 3 properties and 1 level of inheritance, but many real-world examples of these types of hierarchies go many levels deeper, accumulating larger and larger numbers of properties to pass along as they do so. Roslyn is one such codebase, for example, in the various tree types that make our CSTs and ASTs. This nesting is tedious enough that we have code generators to generate the constructors and definitions of these types, and many customers take similar approaches to the problem. C# 9 introduces records, which for some scenarios can make this better:

C#

```
record Person(string FirstName, string LastName, string MiddleName = "");  
record Student(int ID, string FirstName, string LastName, string MiddleName  
= "") : Person(FirstName, LastName, MiddleName);
```

records eliminate the first source of duplication, but the second source of duplication remains unchanged: unfortunately, this is the source of duplication that grows as the hierarchy grows, and is the most painful part of the duplication to fix up after making a change in the hierarchy as it required chasing the hierarchy through all of its locations, possibly even across projects and potentially breaking consumers.

As a workaround to avoid this duplication, we have long seen consumers embracing object initializers as a way of avoiding writing constructors. Prior to C# 9, however, this had 2 major downsides:

1. The object hierarchy has to be fully mutable, with `set` accessors on every property.
2. There is no way to ensure that every instantiation of an object from the graph sets every member.

C# 9 again addressed the first issue here, by introducing the `init` accessor: with it, these properties can be set on object creation/initialization, but not subsequently. However, we again still have the second issue: properties in C# have been optional since C# 1.0. Nullable reference types, introduced in C# 8.0, addressed part of this issue: if a constructor does not initialize a non-nullable reference-type property, then the user is warned about it. However, this doesn't solve the problem: the user here wants to not repeat large parts of their type in the constructor, they want to pass the *requirement* to set properties on to their consumers. It also doesn't provide any warnings about `ID` from `Student`, as that is a value type. These scenarios are extremely common in database model ORMs, such as EF Core, which need to have a public parameterless

constructor but then drive nullability of the rows based on the nullability of the properties.

This proposal seeks to address these concerns by introducing a new feature to C#: required members. Required members will be required to be initialized by consumers, rather than by the type author, with various customizations to allow flexibility for multiple constructors and other scenarios.

Detailed Design

`class`, `struct`, and `record` types gain the ability to declare a *required_member_list*. This list is the list of all the properties and fields of a type that are considered *required*, and must be initialized during the construction and initialization of an instance of the type. Types inherit these lists from their base types automatically, providing a seamless experience that removes boilerplate and repetitive code.

required modifier

We add `'required'` to the list of modifiers in *field_modifier* and *property_modifier*. The *required_member_list* of a type is composed of all the members that have had `required` applied to them. Thus, the `Person` type from earlier now looks like this:

C#

```
public class Person
{
    // The default constructor requires that FirstName and LastName be set
    at construction time
    public required string FirstName { get; init; }
    public string MiddleName { get; init; } = "";
    public required string LastName { get; init; }
}
```

All constructors on a type that has a *required_member_list* automatically advertise a *contract* that consumers of the type must initialize all of the properties in the list. It is an error for a constructor to advertise a contract that requires a member that is not at least as accessible as the constructor itself. For example:

C#

```
public class C
{
    public required int Prop { get; protected init; }
```

```

// Advertises that Prop is required. This is fine, because the
constructor is just as accessible as the property initer.
protected C() {}

// Error: ctor C(object) is more accessible than required property
Prop.init.
public C(object otherArg) {}
}

```

`required` is only valid in `class`, `struct`, and `record` types. It is not valid in `interface` types. `required` cannot be combined with the following modifiers:

- `fixed`
- `ref readonly`
- `ref`
- `const`
- `static`

`required` is not allowed to be applied to indexers.

The compiler will issue a warning when `obsolete` is applied to a required member of a type and:

1. The type is not marked `obsolete`, or
2. Any constructor not attributed with `SetsRequiredMembersAttribute` is not marked `obsolete`.

SetsRequiredMembersAttribute

All constructors in a type with required members, or whose base type specifies required members, must have those members set by a consumer when that constructor is called. In order to exempt constructors from this requirement, a constructor can be attributed with `SetsRequiredMembersAttribute`, which removes these requirements. The constructor body is not validated to ensure that it definitely sets the required members of the type.

`SetsRequiredMembersAttribute` removes *all* requirements from a constructor, and those requirements are not checked for validity in any way. NB: this is the escape hatch if inheriting from a type with an invalid required members list is necessary: mark the constructor of that type with `SetsRequiredMembersAttribute`, and no errors will be reported.

If a constructor `C` chains to a `base` or `this` constructor that is attributed with `SetsRequiredMembersAttribute`, `C` must also be attributed with

`SetsRequiredMembersAttribute`.

For record types, we will emit `SetsRequiredMembersAttribute` on the synthesized copy constructor of a record if the record type or any of its base types have required members.

NB: An earlier version of this proposal had a larger metalanguage around initialization, allowing adding and removing individual required members from a constructor, as well as validation that the constructor was setting all required members. This was deemed too complex for the initial release, and removed. We can look at adding more complex contracts and modifications as a later feature.

Enforcement

For every constructor `ci` in type `T` with required members `R`, consumers calling `ci` must do one of:

- Set all members of `R` in an *object_initializer* on the *object_creation_expression*,
- Or set all members of `R` via the *named_argument_list* section of an *attribute_target*.

unless `ci` is attributed with `SetsRequiredMembers`.

If the current context does not permit an *object_initializer* or is not an *attribute_target*, and `ci` is not attributed with `SetsRequiredMembers`, then it is an error to call `ci`.

`new()` constraint

A type with a parameterless constructor that advertises a *contract* is not allowed to be substituted for a type parameter constrained to `new()`, as there is no way for the generic instantiation to ensure that the requirements are satisfied.

Accessibility

It is an error to mark a member required if the member cannot be set in any context where the containing type is visible.

- If the member is a field, it cannot be `readonly`.
- If the member is a property, it must have a setter or initer at least as accessible as the member's containing type.

This means the following cases are not allowed:

C#

```
interface I
{
    int Prop1 { get; }
}
public class Base
{
    public virtual int Prop2 { get; set; }

    protected required int _field; // Error: _field is not at least as
    visible as Base. Open question below about the protected constructor
    scenario

    public required readonly int _field2; // Error: required fields cannot
    be readonly
    protected Base() { }

    protected class Inner
    {
        protected required int PropInner { get; set; } // Error: PropInner
        cannot be set inside Base or Derived
    }
}
public class Derived : Base, I
{
    required int I.Prop1 { get; } // Error: explicit interface implementations
    cannot be required as they cannot be set in an object initializer

    public required override int Prop2 { get; set; } // Error: this property
    is hidden by Derived.Prop2 and cannot be set in an object initializer
    public new int Prop2 { get; }

    public required int Prop3 { get; } // Error: Required member must have a
    setter or initer

    public required int Prop4 { get; internal set; } // Error: Required
    member setter must be at least as visible as the constructor of Derived
}
```

It is an error to hide a `required` member, as that member can no longer be set by a consumer.

When overriding a `required` member, the `required` keyword must be included on the method signature. This is done so that if we ever want to allow unrequiring a property with an override in the future, we have design space to do so.

Overrides are allowed to mark a member `required` where it was not `required` in the base type. A member so-marked is added to the required members list of the derived type.

Types are allowed to override required virtual properties. This means that if the base virtual property has storage, and the derived type tries to access the base implementation of that property, they could observe uninitialized storage. NB: This is a general C# anti-pattern, and we don't think that this proposal should attempt to address it.

Effect on nullable analysis

Members that are marked `required` are not required to be initialized to a valid nullable state at the end of a constructor. All `required` members from this type and any base types are considered by nullable analysis to be default at the beginning of any constructor in that type, unless chaining to a `this` or `base` constructor that is attributed with `SetsRequiredMembersAttribute`.

Nullable analysis will warn about all `required` members from the current and base types that do not have a valid nullable state at the end of a constructor attributed with `SetsRequiredMembersAttribute`.

C#

```
#nullable enable
public class Base
{
    public required string Prop1 { get; set; }

    public Base() {}

    [SetsRequiredMembers]
    public Base(int unused) { Prop1 = ""; }
}
public class Derived : Base
{
    public required string Prop2 { get; set; }

    [SetsRequiredMembers]
    public Derived() : base()
    {
        } // Warning: Prop1 and Prop2 are possibly null.

    [SetsRequiredMembers]
    public Derived(int unused) : base()
    {
        Prop1.ToString(); // Warning: possibly null dereference
        Prop2.ToString(); // Warning: possibly null dereference
    }

    [SetsRequiredMembers]
    public Derived(int unused, int unused2) : this()
```

```

{
    Prop1.ToString(); // Ok
    Prop2.ToString(); // Ok
}

[SetsRequiredMembers]
public Derived(int unused1, int unused2, int unused3) : base(unused1)
{
    Prop1.ToString(); // Ok
    Prop2.ToString(); // Warning: possibly null dereference
}
}

```

Metadata Representation

The following 2 attributes are known to the C# compiler and required for this feature to function:

```

C#

namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Class | AttributeTargets.Struct |
AttributeTargets.Field | AttributeTargets.Property, AllowMultiple = false,
Inherited = false)]
    public sealed class RequiredMemberAttribute : Attribute
    {
        public RequiredMemberAttribute() {}
    }
}

namespace System.Diagnostics.CodeAnalysis
{
    [AttributeUsage(AttributeTargets.Constructor, AllowMultiple = false,
Inherited = false)]
    public sealed class SetsRequiredMembersAttribute : Attribute
    {
        public SetsRequiredMembersAttribute() {}
    }
}

```

It is an error to manually apply `RequiredMemberAttribute` to a type.

Any member that is marked `required` has a `RequiredMemberAttribute` applied to it. In addition, any type that defines such members is marked with `RequiredMemberAttribute`, as a marker to indicate that there are required members in this type. Note that if type `B` derives from `A`, and `A` defines `required` members but `B` does not add any new or override any existing `required` members, `B` will not be marked with a

`RequiredMemberAttribute`. To fully determine whether there are any required members in `B`, checking the full inheritance hierarchy is necessary.

Any constructor in a type with `required` members that does not have `SetsRequiredMembersAttribute` applied to it is marked with two attributes:

1. `System.Runtime.CompilerServices.CompilerFeatureRequiredAttribute` with the feature name `"RequiredMembers"`.
2. `System.ObsoleteAttribute` with the string `"Types with required members are not supported in this version of your compiler"`, and the attribute is marked as an error, to prevent any older compilers from using these constructors.

We don't use a `modreq` here because it is a goal to maintain binary compat: if the last `required` property was removed from a type, the compiler would no longer synthesize this `modreq`, which is a binary-breaking change and all consumers would need to be recompiled. A compiler that understands `required` members will ignore this obsolete attribute. Note that members can come from base types as well: even if there are no new `required` members in the current type, if any base type has `required` members, this `Obsolete` attribute will be generated. If the constructor already has an `Obsolete` attribute, no additional `Obsolete` attribute will be generated.

We use both `ObsoleteAttribute` and `CompilerFeatureRequiredAttribute` because the latter is new this release, and older compilers don't understand it. In the future, we may be able to drop the `ObsoleteAttribute` and/or not use it to protect new features, but for now we need both for full protection.

To build the full list of `required` members `R` for a given type `T`, including all base types, the following algorithm is run:

1. For every `Tb`, starting with `T` and working through the base type chain until `object` is reached.
2. If `Tb` is marked with `RequiredMemberAttribute`, then all members of `Tb` marked with `RequiredMemberAttribute` are gathered into `Rb`
 - a. For every `Ri` in `Rb`, if `Ri` is overridden by any member of `R`, it is skipped.
 - b. Otherwise, if any `Ri` is hidden by a member of `R`, then the lookup of required members fails and no further steps are taken. Calling any constructor of `T` not attributed with `SetsRequiredMembers` issues an error.
 - c. Otherwise, `Ri` is added to `R`.

Open Questions

Nested member initializers

What will the enforcement mechanisms for nested member initializers be? Will they be disallowed entirely?

C#

```
class Range
{
    public required Location Start { get; init; }
    public required Location End { get; init; }
}

class Location
{
    public required int Column { get; init; }
    public required int Line { get; init; }
}

_ = new Range { Start = { Column = 0, Line = 0 }, End = { Column = 1, Line = 0 } } // Would this be allowed if Location is a struct type?
_ = new Range { Start = new Location { Column = 0, Line = 0 }, End = new Location { Column = 1, Line = 0 } } // Or would this form be necessary instead?
```

Discussed Questions

Level of enforcement for `init` clauses

Do we strictly enforce that members specified in a `init` clause without an initializer must initialize all members? It seems likely that we do, otherwise we create an easy pit-of-failure. However, we also run the risk of reintroducing the same problems we solved with `MemberNotNull` in C# 9. If we want to strictly enforce this, we will likely need a way for a helper method to indicate that it sets a member. Some possible syntaxes we've discussed for this:

- Allow `init` methods. These methods are only allowed to be called from a constructor or from another `init` method, and can access `this` as if it's in the constructor (ie, set `readonly` and `init` fields/properties). This can be combined with `init` clauses on such methods. A `init` clause would be considered satisfied if the member in the clause is definitely assigned in the body of the method/constructor. Calling a method with a `init` clause that includes a member counts as assigning to that member. If we do decided that this is a route we want

to pursue, now or in the future, it seems likely that we should not use `init` as the keyword for the init clause on a constructor, as that would be confusing.

- Allow the `!` operator to suppress the warning/error explicitly. If initializing a member in a complicated way (such as in a shared method), the user can add a `!` to the init clause to indicate the compiler should not check for initialization.

Conclusion: After discussion we like the idea of the `!` operator. It allows the user to be intentional about more complicated scenarios while also not creating a large design hole around init methods and annotating every method as setting members X or Y. `!` was chosen because we already use it for suppressing nullable warnings, and using it to tell the compiler "I'm smarter than you" in another place is a natural extension of the syntax form.

Required interface members

This proposal does not allow interfaces to mark members as required. This protects us from having to figure out complex scenarios around `new()` and interface constraints in generics right now, and is directly related to both factories and generic construction. In order to ensure that we have design space in this area, we forbid `required` in interfaces, and forbid types with `required_member_lists` from being substituted for type parameters constrained to `new()`. When we want to take a broader look at generic construction scenarios with factories, we can revisit this issue.

Syntax questions

- Is `init` the right word? `init` as a postfix modifier on the constructor might interfere if we ever want to reuse it for factories and also enable `init` methods with a prefix modifier. Other possibilities:
 - `set`
- Is `required` the right modifier for specifying that all members are initialized? Others suggested:
 - `default`
 - `all`
 - With a `!` to indicate complex logic
- Should we require a separator between the `base/this` and the `init`?
 - `:` separator
 - `,` separator
- Is `required` the right modifier? Other alternatives that have been suggested:
 - `req`

- `require`
- `mustinit`
- `must`
- `explicit`

Conclusion: We have removed the `init` constructor clause for now, and are proceeding with `required` as the property modifier.

Init clause restrictions

Should we allow access to `this` in the `init` clause? If we want the assignment in `init` to be a shorthand for assigning the member in the constructor itself, it seems like we should.

Additionally, does it create a new scope, like `base()` does, or does it share the same scope as the method body? This is particularly important for things like local functions, which the `init` clause may want to access, or for name shadowing, if an `init` expression introduces a variable via `out` parameter.

Conclusion: `init` clause has been removed.

Accessibility requirements and `init`

In versions of this proposal with the `init` clause, we talked about being able to have the following scenario:

```
C#  
  
public class Base  
{  
    protected required int _field;  
  
    protected Base() {} // Contract required that _field is set  
}  
public class Derived : Base  
{  
    public Derived() : init(_field = 1) // Contract is fulfilled and _field  
    is removed from the required members list  
    {  
    }  
}
```

However, we have removed the `init` clause from the proposal at this point, so we need to decide whether to allow this scenario in a limited fashion. The options we have are:

1. Disallow the scenario. This is the most conservative approach, and the rules in the [Accessibility](#) are currently written with this assumption in mind. The rule is that any member that is required must be at least as visible as its containing type.
2. Require that all constructors are either:
 - a. No more visible than the least-visible required member.
 - b. Have the `SetsRequiredMembersAttribute` applied to the constructor. These would ensure that anyone who can see a constructor can either set all the things it exports, or there is nothing to set. This could be useful for types that are only ever created via static `Create` methods or similar builders, but the utility seems overall limited.
3. Readd a way to remove specific parts of the contract to the proposal, as discussed in [LDM](#) previously.

Conclusion: Option 1, all required members must be at least as visible as their containing type.

Override rules

The current spec says that the `required` keyword needs to be copied over and that overrides can make a member *more* required, but not less. Is that what we want to do? Allowing removal of requirements needs more contract modification abilities than we are currently proposing.

Conclusion: Adding `required` on override is allowed. If the overridden member is `required`, the overriding member must also be `required`.

Alternative metadata representation

We could also take a different approach to metadata representation, taking a page from extension methods. We could put a `RequiredMemberAttribute` on the type to indicate that the type contains required members, and then put a `RequiredMemberAttribute` on each member that is required. This would simplify the lookup sequence (no need to do member lookup, just look for members with the attribute).

Conclusion: Alternative approved.

Metadata Representation

The [Metadata Representation](#) needs to be approved. We additionally need to decide whether these attributes should be included in the BCL.

1. For `RequiredMemberAttribute`, this attribute is more akin to the general embedded attributes we use for nullable/nint/tuple member names, and will not be manually applied by the user in C#. It's possible that other languages might want to manually apply this attribute, however.
2. `SetsRequiredMembersAttribute`, on the other hand, is directly used by consumers, and thus should likely be in the BCL.

If we go with the alternative representation in the previous section, that might change the calculus on `RequiredMemberAttribute`: instead of being similar to the general embedded attributes for `nint`/nullable/tuple member names, it's closer to `System.Runtime.CompilerServices.ExtensionAttribute`, which has been in the framework since extension methods shipped.

Conclusion: We will put both attributes in the BCL.

Warning vs Error

Should not setting a required member be a warning or an error? It is certainly possible to trick the system, via `Activator.CreateInstance(typeof(C))` or similar, which means we may not be able to fully guarantee all properties are always set. We also allow suppression of the diagnostics at the constructor-site by using the `!`, which we generally do not allow for errors. However, the feature is similar to readonly fields or init properties, in that we hard error if users attempt to set such a member after initialization, but they can be circumvented by reflection.

Conclusion: Errors.

Auto-default structs

Article • 2022-09-27 • 6 minutes to read

<https://github.com/dotnet/csharpplang/issues/5737>

Summary

This feature makes it so that in struct constructors, we identify fields which were not explicitly assigned by the user before returning or before use, and initialize them implicitly to `default` instead of giving definite assignment errors.

Motivation

This proposal is raised as a possible mitigation for usability issues found in [dotnet/csharpplang#5552](#) and [dotnet/csharpplang#5635](#), as well as addressing [#5563](#) (all fields must be definitely assigned, but `field` is not accessible within the constructor).

Since C# 1.0, struct constructors have been required to definitely assign `this` as if it were an `out` parameter.

C#

```
public struct S
{
    public int x, y;
    public S() // error: Fields 'S.x' and 'S.y' must be fully assigned
before control is returned to the caller
    {
    }
}
```

This presents issues when setters are manually defined on semi-auto properties, since the compiler can't treat assignment of the property as equivalent to assignment of the backing field.

C#

```
public struct S
{
    public int X { get => field; set => field = value; }
    public S() // error: struct fields aren't fully assigned. But caller can
only assign 'this.field' by assigning 'this'.
    {
```

```
}  
}
```

We assume that introducing finer-grained restrictions for setters, such as a scheme where the setter doesn't take `ref this` but rather takes `out field` as a parameter, is going to be too niche and incomplete for some use cases.

One fundamental tension we are struggling with is that when struct properties have manually implemented setters, users often have to do some form of "repetition" of either repeatedly assigning or repeating their logic:

```
C#  
  
struct S  
{  
    private int _x;  
    public int X  
    {  
        get => _x;  
        set => _x = value >= 0 ? value : throw new  
ArgumentOutOfRangeException();  
    }  
  
    // Solution 1: assign some value in the constructor before "really"  
assigning through the property setter.  
    public S(int x)  
    {  
        _x = default;  
        X = x;  
    }  
  
    // Solution 2: assign the field once in the constructor, repeating the  
implementation of the setter.  
    public S(int x)  
    {  
        _x = x >= 0 ? x : throw new ArgumentOutOfRangeException();  
    }  
}
```

Previous discussion

A small group has looked at this issue and considered a few possible solutions:

1. Require users to assign `this = default` when semi-auto properties have manually implemented setters. We agree this is the wrong solution since it blows away values set in field initializers.
2. Implicitly initialize all backing fields of auto/semi-auto properties.

- This solves the "semi-auto property setters" problem, and it squarely places explicitly declared fields under different rules: "don't implicitly initialize my fields, but do implicitly initialize my auto-properties."

3. Provide a way to assign the backing field of a semi-auto property and require users to assign it.

- This could be cumbersome compared to (2). An auto property is supposed to be "automatic", and perhaps that includes "automatic" initialization of the field. It could introduce confusion as to when the underlying field is being assigned by an assignment to the property, and when the property setter is being called.

We've also received [feedback](#) from users who want to, for example, include a few field initializers in structs without having to explicitly assign everything. We can solve this issue as well as the "semi-auto property with manually implemented setter" issue at the same time.

C#

```
struct MagnitudeVector3d
{
    double X, Y, Z;
    double Magnitude = 1;
    public MagnitudeVector3d() // error: must assign 'X', 'Y', 'Z' before
returning
    {
    }
}
```

Adjusting definite assignment

Instead of performing a definite assignment analysis to give errors for unassigned fields on `this`, we do it to determine *which fields need to be initialized implicitly*. Such initialization is inserted at the *beginning of the constructor*.

C#

```
struct S
{
    int x, y;

    // Example 1
    public S()
    {
        // ok. Compiler inserts an assignment of `this = default`.
    }
}
```

```

}

// Example 2
public S()
{
    // ok. Compiler inserts an assignment of `y = default`.
    x = 1;
}

// Example 3
public S()
{
    // valid since C# 1.0. Compiler inserts no implicit assignments.
    x = 1;
    y = 2;
}

// Example 4
public S(bool b)
{
    // ok. Compiler inserts assignment of `this = default`.
    if (b)
        x = 1;
    else
        y = 2;
}

// Example 5
void M() { }
public S(bool b)
{
    // ok. Compiler inserts assignment of `y = default`.
    x = 1;
    if (b)
        M();

    y = 2;
}
}

```

In examples (4) and (5), the resulting codegen sometimes has "double assignments" of fields. This is generally fine, but for users who are concerned with such double assignments, we can emit what used to be definite assignment error diagnostics as *disabled-by-default* warning diagnostics.

C#

```

struct S
{
    int x;
    public S() // warning: 'S.x' is implicitly initialized to 'default'.
    {

```

```
}  
}
```

Users who set the severity of this diagnostic to "error" will opt in to the pre-C# 11 behavior. Such users are essentially "shut out" of semi-auto properties with manually implemented setters.

```
C#
```

```
struct S  
{  
    public int X  
    {  
        get => field;  
        set => field = field < value ? value : field;  
    }  
  
    public S() // error: backing field of 'S.X' is implicitly initialized to  
    'default'.  
    {  
        X = 1;  
    }  
}
```

At first glance, this feels like a "hole" in the feature, but it's **actually the right thing to do**. By enabling the diagnostic, the user is telling us that they don't want the compiler to implicitly initialize their fields in the constructor. There's no way to avoid the implicit initialization here, so the solution for them is to use a different way of initializing the field than a manually implemented setter, such as manually declaring the field and assigning it, or by including a field initializer.

Currently, the JIT does not eliminate dead stores through refs, which means that these implicit initializations do have a real cost. But that might be fixable.

<https://github.com/dotnet/runtime/issues/13727> ↗

It's worth noting that initializing individual fields instead of the entire instance is really just an optimization. The compiler should probably be free to implement whatever heuristic it wants, as long as it meets the invariant that fields which are not definitely assigned at all return points or before any non-field member access of `this` are implicitly initialized.

For example, if a struct has 100 fields, and just one of them is explicitly initialized, it might make more sense to do an `initobj` on the entire thing, than to implicitly emit `initobj` for the 99 other fields. However, an implementation which implicitly emits `initobj` for the 99 other fields would still be valid.

Changes to language specification

We adjust the following section of the standard:

<https://github.com/dotnet/csharpstandard/blob/draft-v6/standard/expressions.md#11712-this-access> ↗

If the constructor declaration has no constructor initializer, the `this` variable behaves exactly the same as an `out` parameter of the struct type. In particular, this means that the variable shall be definitely assigned in every execution path of the instance constructor.

We adjust this language to read:

If the constructor declaration has no constructor initializer, the `this` variable behaves similarly to an `out` parameter of the struct type, except that it is not an error when the definite assignment requirements (§9.4.1 ↗) are not met. Instead, we introduce the following behaviors:

1. When the `this` variable itself does not meet the requirements, then all unassigned instance variables within `this` at all points where requirements are violated are implicitly initialized to the default value (§9.3 ↗) in an *initialization* phase before any other code in the constructor runs.
2. When an instance variable `v` within `this` does not meet the requirements, or any instance variable at any level of nesting within `v` does not meet the requirements, then `v` is implicitly initialized to the default value in an *initialization* phase before any other code in the constructor runs.

Design meetings

<https://github.com/dotnet/csharplang/blob/main/meetings/2022/LDM-2022-02-14.md#definite-assignment-in-structs> ↗

Low Level Struct Improvements

Article • 2022-12-13 • 73 minutes to read

Summary

This proposal is an aggregation of several different proposals for `struct` performance improvements: `ref` fields and the ability to override lifetime defaults. The goal being a design which takes into account the various proposals to create a single overarching feature set for low level `struct` improvements.

Motivation

Earlier versions of C# added a number of low level performance features to the language: `ref` returns, `ref struct`, function pointers, etc. ... These enabled .NET developers to write highly performant code while continuing to leverage the C# language rules for type and memory safety. It also allowed the creation of fundamental performance types in the .NET libraries like `Span<T>`.

As these features have gained traction in the .NET ecosystem developers, both internal and external, have been providing us with information on remaining friction points in the ecosystem. Places where they still need to drop to `unsafe` code to get their work done, or require the runtime to special case types like `Span<T>`.

Today `Span<T>` is accomplished by using the `internal` type `ByReference<T>` which the runtime effectively treats as a `ref` field. This provides the benefit of `ref` fields but with the downside that the language provides no safety verification for it, as it does for other uses of `ref`. Further only dotnet/runtime can use this type as it's `internal`, so 3rd parties can not design their own primitives based on `ref` fields. Part of the [motivation for this work](#) is to remove `ByReference<T>` and use proper `ref` fields in all code bases.

This proposal plans to address these issues by building on top of our existing low level features. Specifically it aims to:

- Allow `ref struct` types to declare `ref` fields.
- Allow the runtime to fully define `Span<T>` using the C# type system and remove special case type like `ByReference<T>`
- Allow `struct` types to return `ref` to their fields.
- Allow runtime to remove `unsafe` uses caused by limitations of lifetime defaults

- Allow the declaration of safe `fixed` buffers for managed and unmanaged types in `struct`

Detailed Design

The rules for `ref struct` safety are defined in the [span safety document](#). This document will describe the required changes to this document as a result of this proposal. Once accepted as an approved feature these changes will be incorporated into that document.

Once this design is complete our `Span<T>` definition will be as follows:

```
c#  
  
readonly ref struct Span<T>  
{  
    readonly ref T _field;  
    readonly int _length;  
  
    // This constructor does not exist today but will be added as a part  
    // of changing Span<T> to have ref fields. It is a convenient, and  
    // safe, way to create a length one span over a stack value that today  
    // requires unsafe code.  
    public Span(ref T value)  
    {  
        _field = ref value;  
        _length = 1;  
    }  
}
```

Provide ref fields and scoped

The language will allow developers to declare `ref` fields inside of a `ref struct`. This can be useful for example when encapsulating large mutable `struct` instances or defining high performance types like `Span<T>` in libraries besides the runtime.

```
C#  
  
ref struct S  
{  
    public ref int Value;  
}
```

A `ref` field will be emitted into metadata using the `ELEMENT_TYPE_BYREF` signature. This is no different than how we emit `ref` locals or `ref` arguments. For example `ref int`

`_field` will be emitted as `ELEMENT_TYPE_BYREF ELEMENT_TYPE_I4`. This will require us to update ECMA335 to allow this entry but this should be rather straight forward.

Developers can continue to initialize a `ref struct` with a `ref` field using the `default` expression in which case all declared `ref` fields will have the value `null`. Any attempt to use such fields will result in a `NullReferenceException` being thrown.

```
c#
```

```
ref struct S
{
    public ref int Value;
}

S local = default;
local.Value.ToString(); // throws NullReferenceException
```

While the C# language pretends that a `ref` cannot be `null` this is legal at the runtime level and has well defined semantics. Developers who introduce `ref` fields into their types need to be aware of this possibility and should be **strongly** discouraged from leaking this detail into consuming code. Instead `ref` fields should be validated as non-null using the [runtime helpers](#) and throwing when an uninitialized `struct` is used incorrectly.

```
c#
```

```
ref struct S1
{
    private ref int Value;

    public int GetValue()
    {
        if (System.Runtime.CompilerServices.Unsafe.IsNullRef(ref Value))
        {
            throw new InvalidOperationException(...);
        }

        return Value;
    }
}
```

A `ref` field can be combined with `readonly` modifiers in the following ways:

- `readonly ref`: this is a field that cannot be ref reassigned outside a constructor or `init` methods. It can be value assigned though outside those contexts

- `ref readonly`: this is a field that can be ref reassigned but cannot be value assigned at any point. This how an `in` parameter could be ref reassigned to a `ref` field.
- `readonly ref readonly`: a combination of `ref readonly` and `readonly ref`.

```
c#
ref struct ReadOnlyExample
{
    ref readonly int Field1;
    readonly ref int Field2;
    readonly ref readonly int Field3;

    void Uses(int[] array)
    {
        Field1 = ref array[0]; // Okay
        Field1 = array[0];    // Error: can't assign ref readonly value
        (value is readonly)
        Field2 = ref array[0]; // Error: can't repoint readonly ref
        Field2 = array[0];    // Okay
        Field3 = ref array[0]; // Error: can't repoint readonly ref
        Field3 = array[0];    // Error: can't assign ref readonly value
        (value is readonly)
    }
}
```

A `readonly ref struct` will require that `ref` fields are declared `readonly ref`. There is no requirement that they are declared `readonly ref readonly`. This does allow a `readonly struct` to have indirect mutations via such a field but that is no different than a `readonly` field that pointed to a reference type today ([more details](#))

A `readonly ref` will be emitted to metadata using the `initonly` flag, same as any other field. A `ref readonly` field will be attributed with `System.Runtime.CompilerServices.IsReadOnlyAttribute`. A `readonly ref readonly` will be emitted with both items.

This feature requires runtime support and changes to the ECMA spec. As such these will only be enabled when the corresponding feature flag is set in corelib. The issue tracking the exact API is tracked here <https://github.com/dotnet/runtime/issues/64165>

The set of changes to our span safety rules necessary to allow `ref` fields is small and targeted. The rules already account for `ref` fields existing and being consumed from APIs. The changes need to focus on only two aspects: how they are created and how they are ref reassigned.

First the rules establishing *ref-safe-to-escape* values for fields need to be updated for `ref` fields as follows:

An expression in the form `ref e.F` *ref-safe-to-escape* as follows:

1. If `F` is a `ref` field its *ref-safe-to-escape* scope is the *safe-to-escape* scope of `e`.
2. Else if `e` is of a reference type, it has *ref-safe-to-escape* of *calling method*
3. Else its *ref-safe-to-escape* is taken from the *ref-safe-to-escape* of `e`.

This does not represent a rule change though as the rules have always accounted for `ref` state to exist inside a `ref struct`. This is in fact how the `ref` state in `Span<T>` has always worked and the consumption rules correctly account for this. The change here is just accounting for developers to be able to access `ref` fields directly and ensure they do so by the existing rules implicitly applied to `Span<T>`.

This does mean though that `ref` fields can be returned as `ref` from a `ref struct` but normal fields cannot.

```
c#  
  
ref struct RS  
{  
    ref int _refField;  
    int _field;  
  
    // Okay: this falls into bullet one above.  
    public ref int Prop1 => ref _refField;  
  
    // Error: This is bullet four above and the ref-safe-to-escape of `this`  
    // in a `struct` is the current method scope.  
    public ref int Prop2 => ref _field;  
}
```

This may seem like an error at first glance but this is a deliberate design point. Again though, this is not a new rule being created by this proposal, it is instead acknowledging the existing rules `Span<T>` behaved by now that developers can declare their own `ref` state.

Next the rules for `ref` reassignment need to be adjusted for the presence of `ref` fields. The primary scenario for `ref` reassignment is `ref struct` constructors storing `ref` parameters into `ref` fields. The support will be more general but this is the core scenario. To support this the rules for `ref` reassignment will be adjusted to account for `ref` fields as follows:

Ref reassignment rules

The left operand of the `= ref` operator must be an expression that binds to a ref local variable, a ref parameter (other than `this`), an out parameter, or a ref field.

For a ref reassignment in the form `e1 = ref e2` both of the following must be true:

1. `e2` must have *ref-safe-to-escape* at least as large as the *ref-safe-to-escape* of `e1`
2. `e1` must have the same *safe-to-escape* as `e2` [Note](#)

That means the desired `Span<T>` constructor works without any extra annotation:

c#

```
readonly ref struct Span<T>
{
    readonly ref T _field;
    readonly int _length;

    public Span(ref T value)
    {
        // Falls into the `x.e1 = ref e2` case, where `x` is the implicit
        // `this`. The
        // safe-to-escape of `this` is *return only* and ref-safe-to-escape
        // of `value` is
        // *calling method* hence this is legal.
        _field = ref value;
        _length = 1;
    }
}
```

The change to ref reassignment rules means `ref` parameters can now escape from a method as a `ref` field in a `ref struct` value. As discussed in the [compat considerations section](#) this can change the rules for existing APIs that never intended for `ref` parameters to escape as a `ref` field. The lifetime rules for parameters are based solely on their declaration not on their usage. All `ref` and `in` parameters have *ref-safe-to-escape* of *return only* and hence can now be returned by `ref` or a `ref` field. In order to support APIs having `ref` parameters that can be escaping or non-escaping, and thus restore C# 10 call site semantics, the language will introduce limited lifetime annotations.

scoped modifier

The keyword `scoped` will be used to restrict the lifetime of a value. It can be applied to a `ref` or a value that is a `ref struct` and has the impact of restricting the *ref-safe-to-escape* or *safe-to-escape* lifetime, respectively, to the *current method*. For example:

Parameter or Local	<code>ref-safe-to-escape</code>	<code>safe-to-escape</code>
<code>Span<int> s</code>	<i>current method</i>	<i>calling method</i>
<code>scoped Span<int> s</code>	<i>current method</i>	<i>current method</i>
<code>ref Span<int> s</code>	<i>calling method</i>	<i>calling method</i>
<code>scoped ref Span<int> s</code>	<i>current method</i>	<i>calling method</i>

In this relationship the *ref-safe-to-escape* of a value can never exceed the *safe-to-escape*.

This allows for APIs in C# 11 to be annotated such that they have the same rules as C# 10:

```
c#
Span<int> CreateSpan(scoped ref int parameter)
{
    // Just as with C# 10, the implementation of this method isn't relevant
    // to callers.
}

Span<int> BadUseExamples(int parameter)
{
    // Legal in C# 10 and legal in C# 11 due to scoped ref
    return CreateSpan(ref parameter);

    // Legal in C# 10 and legal in C# 11 due to scoped ref
    int local = 42;
    return CreateSpan(ref local);

    // Legal in C# 10 and legal in C# 11 due to scoped ref
    Span<int> span = stackalloc int[42];
    return CreateSpan(ref span[0]);
}
```

The `scoped` annotation also means that the `this` parameter of a `struct` can now be defined as `scoped ref T`. Previously it had to be special cased in the rules as `ref` parameter that had different *ref-safe-to-escape* rules than other `ref` parameters (see all the references to including or excluding the receiver in the span safety rules). Now it can be expressed as a general concept throughout the rules which further simplifies them.

The `scoped` annotation can also be applied to the following locations:

- locals: This annotation sets the lifetime as *safe-to-escape*, or *ref-safe-to-escape* in case of a `ref` local, to of *current method* irrespective of the initializer lifetime.

c#

```
Span<int> ScopedLocalExamples()
{
    // Error: `span` has a safe-to-escape of *current method*. That is true
    // even though the
    // initializer has a safe-to-escape of *calling method*. The annotation
    // overrides the
    // initializer
    scoped Span<int> span = default;
    return span;

    // Okay: the initializer has safe-to-escape of *calling method* hence so
    // does `span2`
    // and the return is legal.
    Span<int> span2 = default;
    return span2;

    // The declarations of `span3` and `span4` are functionally identical
    // because the
    // initializer has a safe-to-escape of *current method* meaning the
    // `scoped` annotation
    // is effectively implied on `span3`
    Span<int> span3 = stackalloc int[42];
    scoped Span<int> span4 = stackalloc int[42];
}
```

Other uses for `scoped` on locals are discussed [below](#).

The `scoped` annotation cannot be applied to any other location including returns, fields, array elements, etc ... Further while `scoped` has impact when applied to any `ref`, `in` or `out` it only has impact when applied to values which are `ref struct`. Having declarations like `scoped int` has no impact because a non `ref struct` is always safe to return. The compiler will create a diagnostic for such cases to avoid developer confusion.

Change the behavior of `out` parameters

To further limit the impact of the compat change of making `ref` and `in` parameters returnable as `ref` fields, the language will change the default *ref-safe-to-escape* value for `out` parameters to be *current method*. Effectively `out` parameters are implicitly `scoped out` going forward. From a compat perspective this means they cannot be returned by `ref`:

```
c#
```

```
ref int Sneaky(out int i)
{
    i = 42;

    // Error: ref-safe-to-escape of out is now the current method
    return ref i;
}
```

This will increase the flexibility of APIs that return `ref struct` values and have `out` parameters because it does not have to consider the parameter being captured by reference anymore. This is important because it's a common pattern in reader style APIs:

```
c#
```

```
Span<byte> Read(Span<byte> buffer, out int read)
{
    // ..
}

Span<int> Use()
{
    var buffer = new byte[256];

    // If we keep current `out` ref-safe-to-escape this is an error. The
    // language must consider
    // the `read` parameter as returnable as a `ref` field
    //
    // If we change `out` ref-safe-to-escape this is legal. The language
    // does not consider the
    // `read` parameter to be returnable hence this is safe
    int read;
    return Read(buffer, out read);
}
```

The language will also no longer consider arguments passed to an `out` parameter to be returnable. Treating the input to an `out` parameter as returnable was extremely confusing to developers. It essentially subverts the intent of `out` by forcing developers to consider the value passed by the caller which is never used except in languages that don't respect `out`. Going forward languages that support `ref struct` must ensure the original value passed to an `out` parameter is never read.

C# achieves this via its definite assignment rules. That both achieves our ref safety rules as well as allowing for existing code which assigns and then returns `out` parameters values.

c#

```
Span<int> StrangeButLegal(out Span<int> span)
{
    span = default;
    return span;
}
```

Together these changes mean the argument to an `out` parameter does not contribute *safe-to-escape* or *ref-safe-to-escape* values to method invocations. This significantly reduces the overall compat impact of `ref` fields as well as simplifies how developers think about `out`. An argument to an `out` parameter does not contribute to the return, it is simply an output.

Infer *safe-to-escape* of declaration expressions

The *safe-to-escape* of a declaration variable from an `out` argument (`M(x, out var y)`) or deconstruction (`((var x, var y) = M())`) is the *narrowest* of the following:

- calling method
- if out variable is marked `scoped`, then the current local scope (i.e. current method or narrower).
- if out variable's type is ref struct, consider all arguments to the containing invocation, including the receiver:
 - STE of any argument where its corresponding parameter is not `out` and has STE of ReturnOnly or wider
 - RSTE of any argument where its corresponding parameter has RSTE of ReturnOnly or wider

See also [Examples of inferred *safe-to-escape* of declaration expressions](#).

Implicitly `scoped` parameters

Overall there are two `ref` location which are implicitly declared as `scoped`:

- `this` on a `struct` instance method
- `out` parameters

The span safety rules will be written in terms of `scoped ref` and `ref`. For span safety purposes an `in` parameter is equivalent to `ref` and `out` is equivalent to `scoped ref`. Both `in` and `out` will only be specifically called out when it is important to the semantic of the rule. Otherwise they are just considered `ref` and `scoped ref` respectively.

When discussing the *ref-safe-to-escape* of arguments that correspond to `in` parameters they will be generalized as `ref` arguments in the spec. In the case the argument is an lvalue then the *ref-safe-to-escape* is that of the lvalue, otherwise it is *current method*. Again `in` will only be called out here when it is important to the semantic of the current rule.

Return-only escape scope

The design also requires that the introduction of a new escape scope: *return only*. This is similar to *calling method* in that it can be returned but it can **only** be returned through a `return` statement.

The details of *return only* is that it's a scope which is greater than *current method* but smaller than *calling method*. An expression provided to a `return` statement must be at least *return only*. As such most existing rules fall out. For example assignment into a `ref` parameter from an expression with a *safe-to-escape* of *return only* will fail because it's smaller than the `ref` parameter's *safe-to-escape* which is *calling method*. The need for this new escape scope will be discussed [below](#).

There are three locations which default to *return only*:

- A `ref` or `in` parameter. This is done in part for `ref struct` to prevent [silly cyclic assignment](#) issues. It is done uniformly though to simplify the model as well as minimize compat changes.
- A `out` parameter for a `ref struct` will have *safe-to-escape* of *return only*. This allows for return and `out` to be equally expressive. This does not have the silly cyclic assignment problem because `out` is implicitly `scoped` so the *ref-safe-to-escape* is still smaller than the *safe-to-escape*.
- A `this` parameter for a `struct` constructor. This falls out due to being modeled as `out` parameters.

Any expression or statement which explicitly returns a value from a method or lambda must have a *safe-to-escape*, and if applicable a *ref-safe-to-escape*, of at least *return only*. That includes `return` statements, expression bodied members and lambda expressions.

Likewise any assignment to an `out` must have a *safe-to-escape* of at least *return only*. This is not a special case though, this just follows from the existing assignment rules.

Note: An expression whose type is not a `ref struct` type always has a *safe-to-return* of *calling method*.

Rules for method invocation

The span safety rules for method invocation will be updated in several ways. The first is by recognizing the impact that `scoped` has on arguments. For a given argument `expr` that is passed to parameter `p`:

1. If `p` is `scoped ref` then `expr` does not contribute *ref-safe-to-escape* when considering arguments.
2. If `p` is `scoped` then `expr` does not contribute *safe-to-escape* when considering arguments.
3. If `p` is `out` then `expr` does not contribute *ref-safe-to-escape* or *safe-to-escape*
[more details](#)

The language "does not contribute" means the arguments are simply not considered when calculating the *ref-safe-to-escape* or *safe-to-escape* value of the method return respectively. That is because the values can't contribute to that lifetime as the `scoped` annotation prevents it.

The method invocation rules can now be simplified. The receiver no longer needs to be special cased, in the case of `struct` it is now simply a `scoped ref T`. The value rules need to change to account for `ref` field returns:

A value resulting from a method invocation `e1.M(e2, ...)`, where `M()` does not return `ref-to-ref-struct`, is *safe-to-escape* from the narrowest of the following scopes:

1. The *calling method*
2. When the return is a `ref struct` the *safe-to-escape* contributed by all argument expressions
3. When the return is a `ref struct` the *ref-safe-to-escape* contributed by all `ref` arguments

If `M()` does return `ref-to-ref-struct`, the *safe-to-escape* is the same as the *safe-to-escape* of all arguments which are `ref-to-ref-struct`. It is an error if there are multiple arguments with different *safe-to-escape* because of [method arguments must match](#).

The `ref` calling rules can be simplified to:

A value resulting from a method invocation `ref e1.M(e2, ...)`, where `M()` does not return `ref-to-ref-struct`, is *ref-safe-to-escape* the narrowest of the following scopes:

1. The *calling method*

2. The *safe-to-escape* contributed by all argument expressions
3. The *ref-safe-to-escape* contributed by all `ref` arguments

If `M()` does return `ref-to-ref-struct`, the *ref-safe-to-escape* is the narrowest *ref-safe-to-escape* contributed by all arguments which are `ref-to-ref-struct`.

This rule now lets us define the two variants of desired methods:

```
c#

Span<int> CreateWithoutCapture(scoped ref int value)
{
    // Error: value Rule 3 specifies that the safe-to-escape be limited to
    // the ref-safe-to-escape
    // of the ref argument. That is the *current method* for value hence
    // this is not allowed.
    return new Span<int>(ref value);
}

Span<int> CreateAndCapture(ref int value)
{
    // Okay: value Rule 3 specifies that the safe-to-escape be limited to
    // the ref-safe-to-escape
    // of the ref argument. That is the *calling method* for value hence
    // this is not allowed.
    return new Span<int>(ref value)
}

Span<int> ComplexScopedRefExample(scoped ref Span<int> span)
{
    // Okay: the safe-to-escape of `span` is *calling method* hence this is
    // legal.
    return span;

    // Okay: the local `refLocal` has a ref-safe-to-escape of *current
    // method* and a
    // safe-to-escape of *calling method*. In the call below it is passed to
    // a
    // parameter that is `scoped ref` which means it does not contribute
    // ref-safe-to-escape. It only contributes its safe-to-escape hence the
    // returned
    // rvalue ends up as safe-to-escape of *calling method*
    Span<int> local = default;
    ref Span<int> refLocal = ref local;
    return ComplexScopedRefExample(ref refLocal);

    // Error: similar analysis as above but the safe-to-escape scope of
    // `stackLocal` is
    // *current method* hence this is illegal
    Span<int> stackLocal = stackalloc int[42];
    return ComplexScopedRefExample(ref stackLocal);
}
```

Method arguments must match

The presence of `ref` fields means the rules around method arguments must match need to be updated as a `ref` parameter can now be stored as a field in a `ref struct` argument to the method. Previously the rule only had to consider another `ref struct` being stored as a field. The impact of this is discussed in [the compat considerations](#). The new rule is ...

For any method invocation `e.M(a1, a2, ... aN)`

1. Calculate the narrowest *safe-to-escape* from:

- *calling method*
- The *safe-to-escape* of all arguments
- The *ref-safe-to-escape* of all ref arguments whose corresponding parameters have a *ref-safe-to-escape* of *calling method*

2. All `ref` arguments of `ref struct` types must be assignable by a value with that *safe-to-escape*. This is a case where `ref` does **not** generalize to include `in` and `out`

For any method invocation `e.M(a1, a2, ... aN)`

1. Calculate the narrowest *safe-to-escape* from:

- *calling method*
- The *safe-to-escape* of all arguments
- The *ref-safe-to-escape* of all ref arguments whose corresponding parameters are not `scoped`

2. All `out` arguments of `ref struct` types must be assignable by a value with that *safe-to-escape*.

The presence of `scoped` allows developers to reduce the friction this rule creates by marking parameters which are not returned as `scoped`. This removes their arguments from (1) in both cases above and provides greater flexibility to callers.

Impact of this change is discussed more deeply [below](#). Overall this will allow developers to make call sites more flexible by annotating non-escaping ref-like values with `scoped`.

Parameter scope variance

The `scoped` modifier and `[UnscopedRef]` attribute (see [below](#)) on parameters also impacts our object overriding, interface implementation and `delegate` conversion rules. The signature for an override, interface implementation or `delegate` conversion can:

- Add `scoped` to a `ref` or `in` parameter
- Add `scoped` to a `ref struct` parameter
- Remove `[UnscopedRef]` from an `out` parameter
- Remove `[UnscopedRef]` from a `ref` parameter of a `ref struct` type

Any other difference with respect to `scoped` or `[UnscopedRef]` is considered a mismatch.

The compiler will report a diagnostic for *unsafe scoped mismatches* across overrides, interface implementations, and delegate conversions when:

- The method returns a `ref struct` or returns a `ref` or `ref readonly`, or the method has a `ref` or `out` parameter of `ref struct` type, and
- The method has at least one additional `ref`, `in`, or `out` parameter, or a parameter of `ref struct` type.

The rules above ignore `this` parameters because `ref struct` instance methods cannot be used for overrides, interface implementations, or delegate conversions.

The diagnostic is reported as an *error* if the mismatched signatures are both using C#11 ref safety rules; otherwise, the diagnostic is a *warning*.

The `scoped` mismatch warning may be reported on a module compiled with C#7.2 ref safety rules where `scoped` is not available. In some such cases, it may be necessary to suppress the warning if the other mismatched signature cannot be modified.

The `scoped` modifier and `[UnscopedRef]` attribute also have the following effects on method signatures:

- The `scoped` modifier and `[UnscopedRef]` attribute do not affect hiding
- Overloads cannot differ only on `scoped` or `[UnscopedRef]`

The section on `ref` field and `scoped` is long so wanted to close with a brief summary of the proposed breaking changes:

- A value that has *ref-safe-to-escape* to the *calling method* is returnable by `ref` or `ref` field.
- A `out` parameter would be considered *safe-to-escape* within the *current method*.

Detailed Notes:

- A `ref` field can only be declared inside of a `ref struct`
- A `ref` field cannot be declared `static`, `volatile` or `const`
- A `ref` field cannot have a type that is `ref struct`
- The reference assembly generation process must preserve the presence of a `ref` field inside a `ref struct`
- A `readonly ref struct` must declare its `ref` fields as `readonly ref`
- For by-ref values the `scoped` modifier must appear before `in`, `out`, or `ref`
- The span safety rules document will be updated as outlined in this document
- The new span safety rules will be in effect when either
 - The core library contains the feature flag indicating support for `ref` fields
 - The `langversion` value is 11 or higher

Syntax

[12.6.2 Local variable declarations](#) [↗](#): added `'scoped'?`.

```
antlr
```

```
local_variable_declaration
    : 'scoped'? local_variable_mode_modifier? local_variable_type
  local_variable_declarators
    ;

local_variable_mode_modifier
    : 'ref' 'readonly'?
    ;
```

[12.9.4 The for statement](#) [↗](#): added `'scoped'?` *indirectly* from `local_variable_declaration`.

[12.9.5 The foreach statement](#) [↗](#): added `'scoped'?`.

```
antlr
```

Sunset restricted types

The compiler has a concept of a set of "restricted types" which is largely undocumented. These types were given a special status because in C# 1.0 there was no general purpose way to express their behavior. Most notably the fact that the types can contain references to the execution stack. Instead the compiler had special knowledge of them and restricted their use to ways that would always be safe: disallowed returns, cannot use as array elements, cannot use in generics, etc ...

Once `ref` fields are available and extended to support `ref struct` these types can be correctly defined in C# using a combination of `ref struct` and `ref` fields. Therefore when the compiler detects that a runtime supports `ref` fields it will no longer have a notion of restricted types. It will instead use the types as they are defined in the code.

To support this our span safety rules will be updated as follows:

- `__makeref` will be treated as a method with the signature `static TypedReference __makeref<T>(ref T value)`
- `__refvalue` will be treated as a method with the signature `static ref T __refvalue<T>(TypedReference tr)`. The expression `__refvalue(tr, int)` will effectively use the second argument as the type parameter.
- `__arglist` as a parameter will have a *ref-safe-to-escape* and *safe-to-escape* of *current method*.
- `__arglist(...)` as an expression will have a *ref-safe-to-escape* and *safe-to-escape* of *current method*.

Conforming runtimes will ensure that `TypedReference`, `RuntimeArgumentHandle` and `ArgIterator` are defined as `ref struct`. Further `TypedReference` must be viewed as having a `ref` field to a `ref struct` for any possible type (it can store any value). That combined with the above rules will ensure references to the stack do not escape beyond their lifetime.

Note: strictly speaking this is a compiler implementation detail vs. part of the language. But given the relationship with `ref` fields it is being included in the language proposal for simplicity.

Provide unscoped

One of the most notable friction points is the inability to return fields by `ref` in instance members of a `struct`. This means developers can't create `ref` returning methods / properties and have to resort to exposing fields directly. This reduces the usefulness of `ref` returns in `struct` where it is often the most desired.

```
c#  
  
struct S  
{  
    int _field;  
  
    // Error: this, and hence _field, can't return by ref  
    public ref int Prop => ref _field;  
}
```

The [rationale](#) for this default is reasonable but there is nothing inherently wrong with a `struct` escaping `this` by reference, it is simply the default chosen by the span safety rules.

To fix this the language will provide the opposite of the `scoped` lifetime annotation by supporting an `UnscopedRefAttribute`. This can be applied to any `ref` and it will change the *ref-safe-to-escape* to be one level wider than its default. For example:

- if applied to a `struct` instance method it will become *return only* where previously it was *containing method*.
- if applied to a `ref` parameter it will become *calling method* where previously it was *return only*

When applying `[UnscopedRef]` to an instance method of a `struct` it has the impact of modifying the implicit `this` parameter. This means `this` acts as an unannotated `ref` of the same type.

```
c#  
  
struct S  
{  
    int field;  
  
    // Error: `field` has the ref-safe-to-escape of `this` which is *current  
    // method* because  
    // it is a `scoped ref`  
    ref int Prop1 => ref field;  
  
    // Okay: `field` has the ref-safe-to-escape of `this` which is *calling  
    // method* because  
    // it is a `ref`
```

```
[UnscopedRef] ref int Prop1 => ref field;
}
```

The annotation can also be placed on `out` parameters to restore them to C# 10 behavior.

```
c#
ref int SneakyOut([UnscopedRef] out int i)
{
    i = 42;
    return ref i;
}
```

For the purposes of span safety rules, such an `[UnscopedRef] out` is considered simply a `ref`. Similar to how `in` is considered `ref` for lifetime purposes.

The `[UnscopedRef]` annotation will be disallowed on `init` members and constructors inside `struct`. Those members are already special with respect to `ref` semantics as they view `readonly` members as mutable. This means taking `ref` to those members appears as a simple `ref`, not `ref readonly`. This is allowed within the boundary of constructors and `init`. Allowing `[UnscopedRef]` would permit such a `ref` to incorrectly escape outside the constructor and permit mutation after `readonly` semantics had taken place.

The attribute type will have the following definition:

```
c#
namespace System.Diagnostics.CodeAnalysis
{
    [AttributeUsage(
        AttributeTargets.Method | AttributeTargets.Property |
        AttributeTargets.Parameter,
        AllowMultiple = false,
        Inherited = false)]
    public sealed class UnscopedRefAttribute : Attribute
    {
    }
}
```

Detailed Notes:

- An instance method or property annotated with `[UnscopedRef]` has *ref-safe-to-escape* of `this` set to the *calling method*.
- A member annotated with `[UnscopedRef]` cannot implement an interface.

- It is an error to use `[UnscopedRef]` on
 - A member that is not declared on a `struct`
 - A `static` member, `init` member or constructor on a `struct`
 - A parameter marked `scoped`
 - A parameter passed by value
 - A parameter passed by reference that is not implicitly scoped

ScopedRefAttribute

The `scoped` annotations will be emitted into metadata via the type `System.Runtime.CompilerServices.ScopedRefAttribute` attribute. The attribute will be matched by namespace-qualified name so the definition does not need to appear in any specific assembly.

The `ScopedRefAttribute` type is for compiler use only - it is not permitted in source. The type declaration is synthesized by the compiler if not already included in the compilation.

The type will have the following definition:

```
c#
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Parameter, AllowMultiple = false,
    Inherited = false)]
    internal sealed class ScopedRefAttribute : Attribute
    {
    }
}
```

The compiler will emit this attribute on the parameter with `scoped` syntax. This will only be emitted when the syntax causes the value to differ from its default state. For example `scoped out` will cause no attribute to be emitted.

RefSafetyRulesAttribute

There are several differences in the *ref safety rules* between C#7.2 and C#11. Any of these differences could result in breaking changes when recompiling with C#11 against references compiled with C#10 or earlier.

1. unscoped `ref/in/out` parameters may escape a method invocation as a `ref` field of a `ref struct` in C#11, not in C#7.2

2. `out` parameters are implicitly scoped in C#11, and unscoped in C#7.2
3. `ref/in` parameters to `ref struct` types are implicitly scoped in C#11, and unscoped in C#7.2

To reduce the chance of breaking changes when recompiling with C#11, we will update the C#11 compiler to use the ref safety rules *for method invocation* that *match the rules that were used to analyze the method declaration*. Essentially, when analyzing a call to a method compiled with an older compiler, the C#11 compiler will use C#7.2 ref safety rules.

To enable this, the compiler will emit a new `[module: RefSafetyRules(11)]` attribute when the module is compiled with `-langversion:11` or higher or compiled with a corlib containing the feature flag for `ref` fields.

The argument to the attribute indicates the language version of the *ref safety rules* used when the module was compiled. The version is currently fixed at `11` regardless of the actual language version passed to the compiler.

The expectation is that future versions of the compiler will update the ref safety rules and emit attributes with distinct versions.

If the compiler loads a module that includes a `[module: RefSafetyRules(version)]` with a `version` other than `11`, the compiler will report a warning for the unrecognized version if there are any calls to methods declared in that module.

When the C#11 compiler *analyzes a method call*:

- If the module containing the method declaration includes `[module: RefSafetyRules(version)]`, regardless of `version`, the method call is analyzed with C#11 rules.
- If the module containing the method declaration is from source, and compiled with `-langversion:11` or with a corlib containing the feature flag for `ref` fields, the method call is analyzed with C#11 rules.
- *If the module containing the method declaration references `System.Runtime { ver: 7.0 }`, the method call is analyzed with C#11 rules. This rule is a temporary mitigation for modules compiled with earlier previews of C#11 / .NET 7 and will be removed later.*
- Otherwise, the method call is analyzed with C#7.2 rules.

A pre-C#11 compiler will ignore any `RefSafetyRulesAttribute` and analyze method calls with C#7.2 rules only.

The `RefSafetyRulesAttribute` will be matched by namespace-qualified name so the definition does not need to appear in any specific assembly.

The `RefSafetyRulesAttribute` type is for compiler use only - it is not permitted in source. The type declaration is synthesized by the compiler if not already included in the compilation.

C#

```
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Module, AllowMultiple = false,
    Inherited = false)]
    internal sealed class RefSafetyRulesAttribute : Attribute
    {
        public RefSafetyRulesAttribute(int version) { Version = version; }
        public readonly int Version;
    }
}
```

Safe fixed size buffers

The language will relax the restrictions on fixed sized arrays such that they can be declared in safe code and the element type can be managed or unmanaged. This will make types like the following legal:

c#

```
internal struct CharBuffer
{
    internal char Data[128];
}
```

These declarations, much like their `unsafe` counter parts, will define a sequence of `N` elements in the containing type. These members can be accessed with an indexer and can also be converted to `Span<T>` and `ReadOnlySpan<T>` instances.

When indexing into a `fixed` buffer of type `T` the `readonly` state of the container must be taken into account. If the container is `readonly` then the indexer returns `ref readonly T` else it returns `ref T`.

Accessing a `fixed` buffer without an indexer has no natural type however it is convertible to `Span<T>` types. In the case the container is `readonly` the buffer is

implicitly convertible to `ReadOnlySpan<T>`, else it can implicitly convert to `Span<T>` or `ReadOnlySpan<T>` (the `Span<T>` conversion is considered *better*).

The resulting `Span<T>` instance will have a length equal to the size declared on the `fixed` buffer. The *safe-to-escape* scope of the returned value will be equal to the *safe-to-escape* scope of the container, just as it would if the backing data was accessed as a field.

For each `fixed` declaration in a type where the element type is `T` the language will generate a corresponding `get` only indexer method whose return type is `ref T`. The indexer will be annotated with the `[UnscopedRef]` attribute as the implementation will be returning fields of the declaring type. The accessibility of the member will match the accessibility on the `fixed` field.

For example, the signature of the indexer for `CharBuffer.Data` will be the following:

```
c#
```

```
[UnscopedRef] internal ref char DataIndexer(int index) => ...;
```

If the provided index is outside the declared bounds of the `fixed` array then an `IndexOutOfRangeException` will be thrown. In the case a constant value is provided then it will be replaced with a direct reference to the appropriate element. Unless the constant is outside the declared bounds in which case a compile time error would occur.

There will also be a named accessor generated for each `fixed` buffer that provides by value `get` and `set` operations. Having this means that `fixed` buffers will more closely resemble existing array semantics by having a `ref` accessor as well as byval `get` and `set` operations. This means compilers will have the same flexibility when emitting code consuming `fixed` buffers as they do when consuming arrays. This should make operations like `await` over `fixed` buffers easier to emit.

This also has the added benefit that it will make `fixed` buffers easier to consume from other languages. Named indexers is a feature that has existed since the 1.0 release of .NET. Even languages which cannot directly emit a named indexer can generally consume them (C# is actually a good example of this).

The backing storage for the buffer will be generated using the `[InlineArray]` attribute. This is a mechanism discussed in [issue 12320](#) which allows specifically for the case of efficiently declaring sequence of fields of the same type. This particular issue is still under active discussion and the expectation is that the implementation of this feature will follow however that discussion goes.

Initializers with `ref` values in `new` and `with` expressions

In section [11.7.15.3 Object initializers](#), we update the grammar to:

```
antlr

initializer_value
  : 'ref' expression // added
  | expression
  | object_or_collection_initializer
  ;
```

In the section for [with expression](#), we update the grammar to:

```
antlr

member_initializer
  : identifier '=' 'ref' expression // added
  | identifier '=' expression
  ;
```

The left operand of the assignment must be an expression that binds to a `ref` field. The right operand must be an expression that yields an lvalue designating a value of the same type as the left operand.

We add a similar rule to [ref local reassignment](#):

If the left operand is a writeable `ref` (i.e. it designates anything other than a `readonly` field), then the right operand must be a writeable lvalue.

The escape rules for [constructor invocations](#) remain:

A `new` expression that invokes a constructor obeys the same rules as a method invocation that is considered to return the type being constructed.

Namely the rules of [method invocation](#) updated above:

An rvalue resulting from a method invocation `e1.M(e2, ...)` is *safe-to-escape* from the smallest of the following scopes:

1. The *calling method*
2. The *safe-to-escape* contributed by all argument expressions
3. When the return is a `ref struct` then *ref-safe-to-escape* contributed by all `ref` arguments

For a `new` expression with initializers, the initializer expressions count as arguments (they contribute their *safe-to-escape*) and the `ref` initializer expressions count as `ref` arguments (they contribute their *ref-safe-to-escape*), recursively.

Changes in unsafe context

Pointer types ([section 22.3](#)) are extended to allow managed types as referent type. Such pointer types are written as a managed type followed by a `*` token. They produce a warning.

The address-of operator ([section 22.6.5](#)) is relaxed to accept a variable with a managed type as its operand.

The `fixed` statement ([section 22.7](#)) is relaxed to accept *fixed_pointer_initializer* that is the address of a variable of managed type `T` or that is an expression of an *array_type* with elements of a managed type `T`.

The stack allocation initializer ([section 22.9](#)) is similarly relaxed.

Considerations

There are considerations other parts of the development stack should consider when evaluating this feature.

Compat Considerations

The challenge in this proposal is the compatibility implications this design has to our [existing span safety rules](#). While those rules fully support the concept of a `ref struct` having `ref` fields they do not allow for APIs, other than `stackalloc`, to capture `ref` state that refers to the stack. The span safety rules have a [hard assumption](#) that a constructor of the form `Span(ref T value)` does not exist. That means the safety rules do not account for a `ref` parameter being able to escape as a `ref` field hence it allows for code like the following.

```
c#
```

```
Span<int> CreateSpan<int>()  
{  
    // This is legal according to the 7.2 span rules because they do not  
    // account  
    // for a constructor in the form Span(ref T value) existing.  
    int local = 42;  
}
```

```
    return new Span<int>(ref local);  
}
```

Effectively there are three ways for a `ref` parameter to escape from a method invocation:

1. By value return
2. By `ref` return
3. By `ref` field in `ref struct` that is returned or passed as `ref` / `out` parameter

The existing rules only account for (1) and (2). They do not account for (3) hence gaps like returning locals as `ref` fields are not accounted for. This design must change the rules to account for (3). This will have a small impact to compatibility for existing APIs. Specifically it will impact APIs that have the following properties.

- Have a `ref struct` in the signature
 - Where the `ref struct` is a return type, `ref` or `out` parameter
 - Has an additional `in` or `ref` parameter excluding the receiver

In C# 10 callers of such APIs never had to consider that `ref` state input to the API could be captured as a `ref` field. That allowed for several patterns to exist, safely in C# 10, that will be unsafe in C# 11 due to the ability for `ref` state to escape as a `ref` field. For example:

```
c#  
  
Span<int> CreateSpan(ref int parameter)  
{  
    // The implementation of this method is irrelevant when considering the  
    // lifetime of the  
    // returned Span<T>. The span safety rules only look at the method  
    // signature, not the  
    // implementation. In C# 10 ref fields didn't exist hence there was no  
    // way for `parameter`  
    // to escape by ref in this method  
}  
  
Span<int> BadUseExamples(int parameter)  
{  
    // Legal in C# 10 but would be illegal with ref fields  
    return CreateSpan(ref parameter);  
  
    // Legal in C# 10 but would be illegal with ref fields  
    int local = 42;  
    return CreateSpan(ref local);  
  
    // Legal in C# 10 but would be illegal with ref fields  
    Span<int> span = stackalloc int[42];
```

```
return CreateSpan(ref span[0]);  
}
```

The impact of this compatibility break is expected to be very small. The impacted API shape made little sense in the absence of `ref` fields hence it is unlikely customers created many of these. Experiments running tools to spot this API shape over existing repositories back up that assertion. The only repository with any significant counts of this shape is [dotnet/runtime](#) and that is because that repo can create `ref` fields via the `ByReference<T>` intrinsic type.

Even so the design must account for such APIs existing because it expresses a valid pattern, just not a common one. Hence the design must give developers the tools to restore the existing lifetime rules when upgrading to C# 10. Specifically it must provide mechanisms that allow developers to annotate `ref` parameters as unable to escape by `ref` or `ref` field. That allows customers to define APIs in C# 11 that have the same C# 10 callsite rules.

Reference Assemblies

A reference assembly for a compilation using features described in this proposal must maintain the elements that convey span safety information. That means all lifetime annotation attributes must be preserved in their original position. Any attempt to replace or omit them can lead to invalid reference assemblies.

Representing `ref` fields is more nuanced. Ideally a `ref` field would appear in a reference assembly as would any other field. However a `ref` field represents a change to the metadata format and that can cause issues with tool chains that are not updated to understand this metadata change. A concrete example is C++/CLI which will likely error if it consumes a `ref` field. Hence it's advantageous if `ref` fields can be omitted from reference assemblies in our core libraries.

A `ref` field by itself has no impact on span safety rules. As a concrete example consider that flipping the existing `Span<T>` definition to use a `ref` field has no impact on consumption. Hence the `ref` itself can be omitted safely. However a `ref` field does have other impacts to consumption that must be preserved:

- A `ref struct` which has a `ref` field is never considered `unmanaged`
- The type of the `ref` field impacts infinite generic expansion rules. Hence if the type of a `ref` field contains a type parameter that must be preserved

Given those rules here is a valid reference assembly transformation for a `ref struct`:

```
c#
```

```
// Impl assembly
ref struct S<T>
{
    ref T _field;
}

// Ref assembly
ref struct S<T>
{
    object _o; // force managed
    T _f; // maintain generic expansion protections
}
```

Open Issues

Change the design to avoid compat breaks

This design proposes several compatibility breaks with our existing span safety rules. Even though the breaks are believed to be minimally impactful significant consideration was given to a design which had no breaking changes.

The compat preserving design though was significantly more complex than this one. In order to preserve compat `ref` fields need distinct lifetimes for the ability to return by `ref` and return by `ref` field. Essentially it requires us to provide *ref-field-safe-to-escape* tracking for all parameters to a method. This needs to be calculated for all expressions and tracked in all values virtually everywhere that *ref-safe-to-escape* is tracked today.

Further this value has relationships with *ref-safe-to-escape*. For example it's non-sensical to have a value can be returned as a `ref` field but not directly as `ref`. That is because `ref` fields can be trivially returned by `ref` already (`ref` state in a `ref struct` can be returned by `ref` even when the containing value cannot). Hence the rules further need constant adjustment to ensure these values are sensible with respect to each other.

Also it means the language needs syntax to represent `ref` parameters that can be returned in three different ways: by `ref` field, by `ref` and by value. The default being returnable by `ref`. Going forward though the more natural return, particularly when `ref struct` are involved is expected to be by `ref` field or `ref`. That means new APIs require an extra syntax annotation to be correct by default. This is undesirable.

These compat changes though will impact methods that have the following properties:

- Have a `Span<T>` or `ref struct`
 - Where the `ref struct` is a return type, `ref` or `out` parameter
 - Has an additional `in` or `ref` parameter (excluding the receiver)

To understand the impact it's helpful to break APIs into categories:

1. Want consumers to account for `ref` being captured as a `ref` field. Prime example is the `Span(ref T value)` constructors
2. Do not want consumers to account for `ref` being captured as a `ref` field. These though break into two categories
 - a. Unsafe APIs. These are APIs inside the `Unsafe` and `MemoryMarshal` types, of which `MemoryMarshal.CreateSpan` is the most prominent. These APIs do capture the `ref` unsafely but they are also known to be unsafe APIs.
 - b. Safe APIs. These are APIs which take `ref` parameters for efficiency but it is not actually captured anywhere. Examples are small but one is `AsnDecoder.ReadEnumeratedBytes`

This change primarily benefits (1) above. These are expected to make up the majority of APIs that take a `ref` and return a `ref struct` going forward. The changes negatively impact (2.1) and (2.2) as it breaks the existing calling semantics because the lifetime rules change.

The APIs in category (2.1) though are largely authored by Microsoft or by developers who stand the most to benefit from `ref` fields (the Tanner's of the world). It is reasonable to assume this class of developers would be amenable to a compatibility tax on upgrade to C# 11 in the form of a few annotations to retain the existing semantics if `ref` fields were provided in return.

The APIs in category (2.2) are the biggest issue. It is unknown how many such APIs exist and it's unclear if these would be more / less frequent in 3rd party code. The expectation is there is a very small number of them, particularly if we take the compat break on `out`. Searches so far have revealed a very small number of these existing in `public` surface area. This is a hard pattern to search for though as it requires semantic analysis. Before taking this change a tool based approach would be needed to verify the assumptions around this impacting a small number of known cases.

For both cases in category (2) though the fix is straight forward. The `ref` parameters that do not want to be considered capturable must add `scoped` to the `ref`. In (2.1) this will likely also force the developer to use `Unsafe` or `MemoryMarshal` but that is expected for unsafe style APIs.

Ideally the language could reduce the impact of silent breaking changes by issuing a warning when an API silently falls into the troublesome behavior. That would be a method that both takes a `ref`, returns `ref struct` but does not actually capture the `ref` in the `ref struct`. The compiler could issue a diagnostic in that case informing developers such `ref` should be annotated as `scoped ref` instead.

Decision This design can be achieved but the resulting feature is more difficult to use to the point the decision was made to take the compat break.

Decision The compiler will provide a warning when a method meets the criteria but does not capture the `ref` parameter as a `ref` field. This should suitably warn customers on upgrade about the potential issues they are creating

Keywords vs. attributes

This design calls for using attributes to annotate the new lifetime rules. This also could've been done just as easily with contextual keywords. For instance `[DoesNotEscape]` could map to `scoped`. However keywords, even the contextual ones, generally must meet a very high bar for inclusion. They take up valuable language real estate and are more prominent parts of the language. This feature, while valuable, is going to serve a minority of C# developers.

On the surface that would seem to favor not using keywords but there are two important points to consider:

1. The annotations will effect program semantics. Having attributes impact program semantics is a line C# is reluctant to cross and it's unclear if this is the feature that should justify the language taking that step.
2. The developers most likely to use this feature intersect strongly with the set of developers that use function pointers. That feature, while also used by a minority of developers, did warrant a new syntax and that decision is still seen as sound.

Taken together this means syntax should be considered.

A rough sketch of the syntax would be:

- `[RefDoesNotEscape]` maps to `scoped ref`
- `[DoesNotEscape]` maps to `scoped`
- `[RefDoesEscape]` maps to `unscoped`

Decision Use syntax for `scoped` and `scoped ref`; use attribute for `unscoped`.

Allow fixed buffer locals

This design allows for safe `fixed` buffers that can support any type. One possible extension here is allowing such `fixed` buffers to be declared as local variables. This would allow a number of existing `stackalloc` operations to be replaced with a `fixed` buffer. It would also expand the set of scenarios we could have stack style allocations as `stackalloc` is limited to unmanaged element types while `fixed` buffers are not.

```
c#  
  
class FixedBufferLocals  
{  
    void Example()  
    {  
        Span<int> span = stackalloc int[42];  
        int buffer[42];  
    }  
}
```

This holds together but does require us to extend the syntax for locals a bit. Unclear if this is or isn't worth the extra complexity. Possible we could decide no for now and bring back later if sufficient need is demonstrated.

Example of where this would be beneficial:

<https://github.com/dotnet/runtime/pull/34149> ↗

Decision hold off on this for now

To use modreqs or not

A decision needs to be made if methods marked with new lifetime attributes should or should not translate to `modreq` in emit. There would be effectively a 1:1 mapping between annotations and `modreq` if this approach was taken.

The rationale for adding a `modreq` is the attributes change the semantics of span safety. Only languages which understand these semantics should be calling the methods in question. Further when applied to OHI scenarios, the lifetimes become a contract that all derived methods must implement. Having the annotations exist without `modreq` can lead to situations where `virtual` method chains with conflicting lifetime annotations are loaded (can happen if only one part of `virtual` chain is compiled and other is not).

The initial span safety work did not use `modreq` but instead relied on languages and the framework to understand. At the same time though all of the elements that contribute

to the span safety rules are a strong part of the method signature: `ref`, `in`, `ref struct`, etc ... Hence any change to the existing rules of a method already results in a binary change to the signature. To give the new lifetime annotations the same impact they will need `modreq` enforcement.

The concern is whether or not this is overkill. It does have the negative impact that making signatures more flexible, by say adding `[DoesNotEscape]` to a parameter, will result in a binary compat change. That trade off means that over time frameworks like BCL likely won't be able to relax such signatures. It could be mitigated to a degree by taking some approach the language does with `in` parameters and only apply `modreq` in virtual positions.

Decision Do not use `modreq` in metadata. The difference between `out` and `ref` is not `modreq` but they now have different span safety lifetimes. There is no real benefit to only half enforcing the rules with `modreq` here.

Allow multi-dimensional fixed buffers

Should the design for `fixed` buffers be extended to include multi-dimensional style arrays? Essentially allowing for declarations like the following:

```
c#  
  
struct Dimensions  
{  
    int array[42, 13];  
}
```

Decision Do not allow for now

Violating scoped

The runtime repository has several non-public APIs that capture `ref` parameters as `ref` fields. These are unsafe because the lifetime of the resulting value is not tracked. For example the `Span<T>(ref T value, int length)` constructor.

The majority of these APIs will likely choose to have proper lifetime tracking on the return which will be achieved simply by updating to C# 11. A few though will want to keep their current semantics of not tracking the return value because their entire intent is to be unsafe. The most notable examples are `MemoryMarshal.CreateSpan` and `MemoryMarshal.CreateReadOnlySpan`. This will be achieved by marking the parameters as `scoped`.

That means the runtime needs an established pattern for unsafely removing `scoped` from a parameter:

1. `Unsafe.AsRef<T>(in T value)` could expand its existing purpose by changing to `scoped in T value`. This would allow it to both remove `in` and `scoped` from parameters. It then becomes the universal "remove ref safety" method
2. Introduce a new method whose entire purpose is to remove `scoped: ref T` `Unsafe.AsUnscoped<T>(scoped in T value)`. This removes `in` as well because if it did not then callers still need a combination of method calls to "remove ref safety" at which point the existing solution is likely sufficient.

Unscoped this by default?

The design only has two locations which are `scoped` by default:

- `this` is `scoped ref`
- `out` is `scoped ref`

The decision on `out` is to significantly reduce the compat burden of `ref` fields and at the same time is a more natural default. It lets developers actually think of `out` as data flowing outward only whereas if it's `ref` then the rules must consider data flowing in both directions. This leads to significant developer confusion.

The decision on `this` is undesirable because it means a `struct` cannot return a field by `ref`. This is an important scenario to high perf developers and the `[UnscopedRef]` attribute was added essentially for this one scenario.

Keywords have a high bar and adding it for a single scenario is suspect. As such thought was given to whether we could avoid this keyword at all by making `this` simply `ref` by default and not `scoped ref`. All members that need `this` to be `scoped ref` could do so by marking the method `scoped` (as a method can be marked `readonly` to create a `readonly ref` today).

On a normal `struct` this is mostly a positive change as it only introduces compat issues when a member has a `ref` return. There are very few of these methods and a tool could spot these and convert them to `scoped` members quickly.

On a `ref struct` this change introduces significantly bigger compat issues. Consider the following:

```

ref struct Sneaky
{
    int Field;
    ref int RefField;

    public void SelfAssign()
    {
        // This pattern of ref reassign to fields on this inside instance
        // methods is now
        // completely legal.
        RefField = ref Field;
    }

    static Sneaky UseExample()
    {
        Sneaky local = default;

        // Error: this is illegal, and must be illegal, by our existing
        // rules as the
        // ref-safe-to-escape of local is now an input into method arguments
        // must match.
        local.SelfAssign();

        // This would be dangerous as local now has a dangerous `ref` but
        // the above
        // prevents us from getting here.
        return local;
    }
}

```

Essentially it would mean all instance method invocations on *mutable* `ref struct` locals would be illegal unless the local was further marked as `scoped`. The rules have to consider the case where fields were ref reassigned to other fields in `this`. A `readonly ref struct` doesn't have this problem because the `readonly` nature prevents ref reassignment. Still this would be a significant back compat breaking change as it would impact virtually every existing mutable `ref struct`.

A `readonly ref struct` though is still problematic once we expand to having `ref` fields to `ref struct`. It allows for the same basic problem by just moving the capture into the value of the `ref` field:

```

c#

readonly ref struct ReadOnlySneaky
{
    readonly int Field;
    readonly ref ReadOnlySpan<int> Span;

    public void SelfAssign()

```

```

{
    // Instance method captures a ref to itself
    Span = new ReadOnlySpan<int>(ref Field, 1);
}
}

```

Some thought was given to the idea of having `this` have different defaults based on the type of `struct` or member. For example:

- `this` as `ref: struct`, `readonly ref struct` or `readonly member`
- `this` as `scoped ref: ref struct` or `readonly ref struct` with `ref` field to `ref struct`

This minimizes compat breaks and maximizes flexibility but at the cost of complicating the story for customers. It also doesn't fully solve the problem because future features, like safe `fixed` buffers, require that a mutable `ref struct` have `ref` returns for fields which don't work by this design alone as it would fall into the `scoped ref` category.

Decision Keep `this` as `scoped ref`

ref fields to ref struct

This feature opens up a new set of ref safety rules because it allows for a `ref` field to refer to a `ref struct`. This generic nature of `ByReference<T>` meant that up until now the runtime could not have such a construct. As a result all of our rules are written under the assumption this is not possible. The `ref` field feature is largely not about making new rules but codifying the existing rules in our system. Allowing `ref` fields to `ref struct` requires us to codify new rules because there are several new scenarios to consider.

The first is that a `readonly ref` is now capable of storing `ref` state. For example:

```

c#
readonly ref struct Container
{
    readonly ref Span<int> Span;

    void Store(Span<int> span)
    {
        Span = span;
    }
}

```

This means when thinking about method arguments must match rules we must consider `readonly ref T` is potential method output when `T` potentially has a `ref` field to a `ref struct`.

The second issue is language must consider a new type of escape scope: *ref-field-safe-to-escape*. All `ref struct` which transitively contain a `ref` field have another escape scope representing the value(s) in the `ref` field(s). In the case of multiple `ref` fields they can be collectively tracked as a single value. The default value for this for parameters is *calling method*.

```
c#  
  
ref struct Nested  
{  
    ref Span<int> Span;  
}  
  
Span<int> M(ref Nested nested) => nested.Span;
```

This value is not related to the escape scope of the container; that is as the container scope gets smaller it has no impact on the *ref-field-safe-to-escape* of the `ref` field values. Further the *ref-field-safe-to-escape* can never be smaller than the *safe-to-escape* of the container.

```
c#  
  
ref struct Nested  
{  
    ref Span<int> Span;  
}  
  
void M(ref Nested nested)  
{  
    scoped ref Nested refLocal = ref nested;  
  
    // the ref-field-safe-to-escape of local is still *calling method* which  
    // means the following  
    // is illegal  
    refLocal.Span = stackalloc int[42];  
  
    scoped Nested valLocal = nested;  
  
    // the ref-field-safe-to-escape of local is still *calling method* which  
    // means the following  
    // is still illegal  
    valLocal.Span = stackalloc int[42];  
}
```

This *ref-field-safe-to-escape-scope* has essentially always existed. Up until now `ref` fields could only point to normal `struct` hence it was trivially collapsed to *calling method*. To support `ref` fields to `ref struct` our existing rules need to be updated to take into account this new escape scope.

Third the rules for ref reassignment need to be updated to ensure that we don't violate *ref-field-safe-to-escape* for the values. Essentially for `x.e1 = ref e2` where the type of `e1` is a `ref struct` the *ref-field-safe-to-escape* must be equal.

These problems are very solvable. The compiler team has sketched out a few versions of these rules and they largely fall out from our existing analysis. The problem is there is no consuming code for such rules that helps prove out their correctness and usability. This makes us very hesitant to add support because of the fear we'll pick wrong defaults and back the runtime into usability corner when it does take advantage of this. This concern is particularly strong because .NET 8 likely pushes us in this direction with `allow T: ref struct` and `Span<Span<T>>`. The rules would be better written if it's done in conjunction with consumption code.

Decision Delay allowing `ref` field to `ref struct` until .NET 8 where we have scenarios that will help drive the rules around these scenarios.

What will make C# 11.0?

The features outlined in this document don't need to be implemented in a single pass. Instead they can be implemented in phases across several language releases in the following buckets:

1. `ref` fields and `scoped`
2. `[UnscopedRef]`
3. `ref` fields to `ref struct`
4. Sunset restricted types
5. fixed sized buffers

What gets implemented in which release is merely a scoping exercise.

Decision Only (1) and (2) made C# 11.0. The rest will be considered in future versions of C#.

Future Considerations

Advanced lifetime annotations

The lifetime annotations in this proposal are limited in that they allow developers to change the default escape / don't escape behavior of values. This does add powerful flexibility to our model but it does not radically change the set of relationships that can be expressed. At the core the C# model is still effectively binary: can a value be returned or not?

That allows limited lifetime relationships to be understood. For example a value that can't be returned from a method has a smaller lifetime than one that can be returned from a method. There is no way to describe the lifetime relationship between values that can be returned from a method though. Specifically there is no way to say that one value has a larger lifetime than the other once it's established both can be returned from a method. The next step in our lifetime evolution would be allowing such relationships to be described.

Other methods such as Rust allow this type of relationship to be expressed and hence can implement handle more complex `scoped` style operations. Our language could similarly benefit if such a feature were included. At the moment there is no motivating pressure to do this but if there is in the future our `scoped` model could be expanded to include it in a fairly straight forward fashion.

Every `scoped` could be assigned a named lifetime by adding a generic style argument to the syntax. For example `scoped<'a>` is a value that has lifetime `'a`. Constraints like `where` could then be used to describe the relationships between these lifetimes.

```
c#  
  
void M(scoped<'a> ref MyStruct s, scoped<'b> Span<int> span)  
    where 'b >= 'a  
{  
    s.Span = span;  
}
```

This method defines two lifetimes `'a` and `'b` and their relationship, specifically that `'b` is greater than `'a`. This allows for the callsite to have more granular rules for how values can be safely passed into methods vs. the more coarse grained rules present today.

Existing samples

[Utf8JsonReader](#) ↗

This particular snippet requires `unsafe` because it runs into issues with passing around a `Span<T>` which can be stack allocated to an instance method on a `ref struct`. Even though this parameter is not captured the language must assume it is and hence needlessly causes friction here.

[Utf8JsonWriter](#) ↗

This snippet wants to mutate a parameter by escaping elements of the data. The escaped data can be stack allocated for efficiency. Even though the parameter is not escaped the compiler assigns it a *safe-to-escape* scope of outside the enclosing method because it is a parameter. This means in order to use stack allocation the implementation must use `unsafe` in order to assign back to the parameter after escaping the data.

Fun Samples

ReadOnlySpan<T>

```
c#
```

```
public readonly ref struct ReadOnlySpan<T>  
{
```

```

readonly ref readonly T _value;
readonly int _length;

public ReadOnlySpan(in T value)
{
    _value = ref value;
    _length = 1;
}
}

```

Frugal list

```

c#

struct FrugalList<T>
{
    private T _item0;
    private T _item1;
    private T _item2;

    public int Count = 3;

    public ref T this[int index]
    {
        [UnscopedRef] get
        {
            switch (index)
            {
                case 0: return ref _item1;
                case 1: return ref _item2;
                case 2: return ref _item3;
                default: throw null;
            }
        }
    }
}

```

Stack based linked list

```

c#

ref struct StackLinkedListNode<T>
{
    T _value;
    ref StackLinkedListNode<T> _next;

    public T Value => _value;

    public bool HasNext => !Unsafe.IsNullRef(ref _next);
}

```

```

public ref StackLinkedListNode<T> Next
{
    get
    {
        if (!HasNext)
        {
            throw new InvalidOperationException("No next node");
        }

        return ref _next;
    }
}

public StackLinkedListNode(T value)
{
    this = default;
    _value = value;
}

public StackLinkedListNode(T value, ref StackLinkedListNode<T> next)
{
    _value = value;
    _next = ref next;
}
}

```

Examples and Notes

Below are a set of examples demonstrating how and why the rules work the way they do. Included are several examples showing dangerous behaviors and how the rules prevent them from happening. It's important to keep these in mind when making adjustments to the proposal.

Ref reassignment and call sites

Demonstrating how [ref reassignment](#) and [method invocation](#) work together.

```

c#

ref struct RS
{
    ref int _refField;

    public ref int Prop => ref _refField;

    public RS(int[] array)
    {
        _refField = ref array[0];
    }
}

```

```

public RS(ref int i)
{
    _refField = ref i;
}

public RS CreateRS() => ...;

public ref int M1(RS rs)
{
    // The call site arguments for Prop contribute here:
    //   - `rs` contributes no ref-safe-to-escape as the corresponding
parameter,
    //     which is `this`, is `scoped ref`
    //   - `rs` contribute safe-to-escape of *calling method*
    //
    // This is an lvalue invocation and the arguments contribute only
safe-to-escape
    // values of *calling method*. That means `local1` is ref-safe-to-
escape to
    // *calling method*
    ref int local1 = ref rs.Prop;

    // Okay: this is legal because `local` has ref-safe-to-escape of
*calling method*
    return ref local1;

    // The arguments contribute here:
    //   - `this` contributes no ref-safe-to-escape as the corresponding
parameter
    //     is `scoped ref`
    //   - `this` contributes safe-to-escape of *calling method*
    //
    // This is an rvalue invocation and following those rules the safe-
to-escape of
    // `local2` will be *calling method*
    RS local2 = CreateRS();

    // Okay: this follows the same analysis as `ref rs.Prop` above
    return ref local2.Prop;

    // The arguments contribute here:
    //   - `local3` contributes ref-safe-to-escape of *current method*
    //   - `local3` contributes safe-to-escape of *calling method*
    //
    // This is an rvalue invocation which returns a `ref struct` and
following those
    // rules the safe-to-escape of `local4` will be *current method*
    int local3 = 42;
    var local4 = new RS(ref local3);

    // Error:
    // The arguments contribute here:
    //   - `local4` contributes no ref-safe-to-escape as the
corresponding parameter

```

```

    // is `scoped ref`
    // - `local4` contributes safe-to-escape of *current method*
    //
    // This is an lvalue invocation and following those rules the ref-
safe-to-escape
    // of the return is *current method*
    return ref local4.Prop1;
}
}

```

Ref reassignment and unsafe escapes

The reason for the following line in the [ref reassignment rules](#) may not be obvious at first glance:

`e1` must have the same *safe-to-escape* as `e2`

This is because the lifetime of the values pointed to by `ref` locations are invariant. The indirection prevents us from allowing any kind of variance here, even to narrower lifetimes. If narrowing is allowed then it opens up the following unsafe code:

```

C#

ref struct RS { }
void Example(ref Span<int> p)
{
    Span<int> local = stackalloc int[42];
    ref Span<int> refLocal = ref local;

    // The safe-to-escape of refLocal is narrower than p. For a non-ref
reassignment
    // this would be allowed as its safe to assign wider lifetimes to
narrower ones.
    // In the case of ref reassignment though this rule prevents it as the
// safe-to-escape values are different.
    refLocal = ref p;

    // If it were allowed this would be legal as the safe-to-escape of
refLocal
    // is *containing method* and that is satisfied by stackalloc. At the
same time
    // it would be assigning through p and escaping the stackalloc to the
calling
    // method
    //
    // This is equivalent of saying p = stackalloc int[13]!!!
    refLocal = stackalloc int[13];
}

```

For a `ref` to non `ref struct` this rule is trivially satisfied as the values all have the same *safe-to-escape* scope. This rule really only comes into play when the value is a `ref struct`.

This behavior of `ref` will also be important in a future where we allow `ref` fields to `ref struct`.

scoped locals

The use of `scoped` on locals will be particularly helpful to code patterns which conditionally assign values with different *safe-to-escape* scope to locals. It means code no longer needs to rely on initialization tricks like `= stackalloc byte[0]` to define a local *safe-to-escape* but now can simply use `scoped`.

```
c#  
  
// Old way  
// Span<byte> span = stackalloc byte[0];  
// New way  
scoped Span<byte> span;  
int len = ...;  
if (len < MaxStackLen)  
{  
    span = stackalloc byte[len];  
}  
else  
{  
    span = new byte[len];  
}
```

This pattern comes up frequently in low level code. When the `ref struct` involved is `Span<T>` the above trick can be used. It is not applicable to other `ref struct` types though and can result in low level code needing to resort to `unsafe` to work around the inability to properly specify the lifetime.

scoped parameter values

One source of repeated friction in low level code is the default escape for parameters is permissive. They are *safe-to-escape* to the *calling method*. This is a sensible default because it lines up with the coding patterns of .NET as a whole. In low level code though there is a larger use of `ref struct` and this default can cause friction with other parts of the span safety rules.

The main friction point occurs because of the [method arguments must match](#) rule. This rule most commonly comes into play with instance methods on `ref struct` where at least one parameter is also a `ref struct`. This is a common pattern in low level code where `ref struct` types commonly leverage `Span<T>` parameters in their methods. For example it will occur on any writer style `ref struct` that uses `Span<T>` to pass around buffers.

This rule exists to prevent scenarios like the following:

```
c#  
  
ref struct RS  
{  
    Span<int> _field;  
    void Set(Span<int> p)  
    {  
        _field = p;  
    }  
  
    static void DangerousCode(ref RS p)  
    {  
        Span<int> span = stackalloc int[] { 42 };  
  
        // Error: if allowed this would let the method return a reference to  
        // the stack  
        p.Set(span);  
    }  
}
```

Essentially this rule exists because the language must assume that all inputs to a method escape to their maximum allowed scope. When there are `ref` or `out` parameters, including the receivers, it's possible for the inputs to escape as fields of those `ref` values (as happens in `RS.Set` above).

In practice though there are many such methods which pass `ref struct` as parameters that never intend to capture them in output. It is just a value that is used within the current method. For example:

```
c#  
  
ref struct JsonReader  
{  
    Span<char> _buffer;  
    int _position;  
  
    internal bool TextEquals(ReadOnlySpan<char> text)  
    {  
        var current = _buffer.Slice(_position, text.Length);
```

```

        return current == text;
    }
}

class C
{
    static void M(ref JsonReader reader)
    {
        Span<char> span = stackalloc char[4];
        span[0] = 'd';
        span[1] = 'o';
        span[2] = 'g';

        // Error: The safe-to-escape of `span` is the current method scope
        // while `reader` is outside the current method scope hence this
fails
        // by the above rule.
        if (reader.TextEquals(span))
        {
            ...
        }
    }
}

```

In order to work around this low level code will resort to `unsafe` tricks to lie to the compiler about the lifetime of their `ref struct`. This significantly reduces the value proposition of `ref struct` as they are meant to be a means to avoid `unsafe` while continuing to write high performance code.

This is where `scoped` is an effective tool on `ref struct` parameters because it removes them from consideration as being returned from the method according to the updated [method arguments must match rule](#). A `ref struct` parameter which is consumed, but never returned, can be labeled as `scoped` to make call sites more flexible.

```

c#

ref struct JsonReader
{
    Span<char> _buffer;
    int _position;

    internal bool TextEquals(scoped ReadOnlySpan<char> text)
    {
        var current = _buffer.Slice(_position, text.Length);
        return current == text;
    }
}

class C
{

```

```

static void M(ref JsonReader reader)
{
    Span<char> span = stackalloc char[4];
    span[0] = 'd';
    span[1] = 'o';
    span[2] = 'g';

    // Okay: the compiler never considers `span` as capturable here
    hence it doesn't
    // contribute to the method arguments must match rule
    if (reader.TextEquals(span))
    {
        ...
    }
}
}

```

Preventing tricky ref assignment from readonly mutation

When a `ref` is taken to a `readonly` field in a constructor or `init` member the type is `ref` not `ref readonly`. This is a long standing behavior that allows for code like the following:

```

c#
struct S
{
    readonly int i;

    public S(string s)
    {
        M(ref i);
    }

    static void M(ref int i){ }
}

```

That does pose a potential problem though if such a `ref` were able to be stored into a `ref` field on the same type. It would allow for direct mutation of a `readonly struct` from an instance member:

```

c#
readonly ref struct S
{
    readonly int i;
    readonly ref int r;
    public S()
    {

```

```

    i = 0;
    r = ref i;
}

public void Oops()
{
    r++;
}

```

The proposal prevents this though because it violates the span safety rules. Consider the following:

- The *ref-safe-to-escape* of `this` is *current method* and *safe-to-escape* is *calling method*. These are both standard for `this` in a `struct` member.
- The *ref-safe-to-escape* of `i` is *current method*. This falls out from the [field lifetimes rules](#). Specifically rule 4.

At that point the line `r = ref i` is illegal by [ref reassignment rules](#).

These rules were not intended to prevent this behavior but do so as a side effect. It's important to keep this in mind for any future rule update to evaluate the impact to scenarios like this.

Silly cyclic assignment

One aspect this design struggled with is how freely a `ref` can be returned from a method. Allowing all `ref` to be returned as freely as normal values is likely what most developers intuitively expect. However it allows for pathological scenarios that the compiler must consider when calculating ref safety. Consider the following:

```

c#

ref struct S
{
    int field;
    ref int refField;

    static void SelfAssign(ref S s)
    {
        s.refField = ref s.field;
    }
}

```

This is not a code pattern that we expect any developers to use. Yet when a `ref` can be returned with the same lifetime as a value it is legal under the rules. The compiler must

consider all legal cases when evaluating a method call and this leads to such APIs being effectively unusable.

```
c#  
  
void M(ref S s)  
{  
    ...  
}  
  
S Usage()  
{  
    // safe-to-escape to calling method  
    S local = default;  
  
    // Error: compiler is forced to assume the worst and concludes a self  
    // assignment  
    // is possible here and must issue an error.  
    M(ref local);  
}
```

To make these APIs usable the compiler ensures that the `ref` lifetime for a `ref` parameter is smaller than lifetime of any references in the associated parameter value. This is the rationale for having *ref-safe-to-escape* for `ref` to `ref struct` be *return only* and `out` be *containing method*. That prevents cyclic assignment because of the difference in lifetimes.

It is also why `[UnscopedRef]` only promotes the *ref-safe-to-escape* of any `ref` to `ref struct` values to *return only* and not *calling method*. Consider that using *calling method* allows for cyclic assignment and would force a viral use of `[UnscopedRef]` for a `ref struct`:

```
c#  
  
ref struct S  
{  
    byte Field;  
  
    [UnscopedRef]  
    public Span<byte> Data => new Span<byte>(ref Field, 1);  
}  
  
void M(ref S s)  
{  
    // Error: passing a scoped ref to [UnscopedRef] ref  
    Span<byte> span = s.Data;  
}
```

This is correctly illegal in that case because the compiler has to consider the pathological case that `S.Data` could cyclic assign via `this`. That forces methods all methods that call `S.Data` to further mark their `ref` parameters as `[UnscopedRef]`. This is viral until the method which creates the value as a local. This is why *return only* exists as an escape scope. It does complicate the spec / implementation but it serves to make the feature significantly more usable.

Note: this cyclic assignment problem does continue to exist for `[UnscopedRef] out` to `ref struct` because that causes the *safe-to-escape* and *ref-safe-to-escape* to be equivalent.

```
c#

ref struct RS
{
    int field;
    ref int refField;
}

void M1(out RS p)
{
    // Error: from method arguments must match:
    // Step 1 would calculate the narrowest escape as *containing method*
    // Step 2 would fail the assignment check because p safe-to-escape is
    // *return only*
    M2(out p);
}

void M2([UnscopedRef] out RS p)
{
    // The lifetimes of LHS and RHS are equivalent here and hence this is
    // legal
    p.refField = ref p.Field;
}
```

In terms of advanced annotations the `[UnscopedRef]` design creates the following:

```
ref struct S { }

// C# code
S Create1(ref S p)
S Create2([UnscopedRef] ref S p)

// Annotation equivalent
scoped<'b> S Create1(scoped<'a> ref scoped<'b> S)
scoped<'a> S Create2(scoped<'a> ref scoped<'b> S)
    where 'b >= 'a
```

readonly cannot be deep through ref fields

Consider the below code sample:

```
c#  
  
ref struct S  
{  
    ref int Field;  
  
    readonly void Method()  
    {  
        // Legal or illegal?  
        Field = 42;  
    }  
}
```

When designing the rules for `ref` fields on `readonly` instances in a vacuum the rules can be validly designed such that the above is legal or illegal. Essentially `readonly` can validly be deep through a `ref` field or it can apply only to the `ref`. Applying only to the `ref` prevents ref reassignment but allows normal assignment which changes the referred to value.

This design does not exist in a vacuum though, it is designing rules for types that already effectively have `ref` fields. The most prominent of which, `Span<T>`, already has a strong dependency on `readonly` not being deep here. Its primary scenario is the ability to assign to the `ref` field through a `readonly` instance.

```
c#  
  
readonly ref struct SpanOfOne  
{  
    readonly ref int Field;  
  
    public ref int this[int index]  
    {  
        get  
        {  
            if (index != 1)  
                throw new Exception();  
            return ref Field;  
        }  
    }  
}
```

This means we must choose the shallow interpretation of `readonly`.

Modeling constructors

One subtle design question is: How are constructors bodies modeled for ref safety? Essentially how is the following constructor analyzed?

```
c#  
  
ref struct S  
{  
    int field;  
  
    public S(ref int f)  
    {  
        field = ref f;  
    }  
}
```

There are roughly two approaches:

1. Model as a `static` method where `this` is a local where its *safe-to-escape* is *calling method*
2. Model as a `static` method where `this` is an `out` parameter.

Further a constructor must meet the following invariants:

1. Ensure that `ref` parameters can be captured as `ref` fields.
2. Ensure that `ref` to fields of `this` cannot be escaped through `ref` parameters. That would violate [tricky ref assignment](#).

The intent is to pick the form that satisfies our invariants without introduction of any special rules for constructors. Given that the best model for constructors is viewing `this` as an `out` parameter. The *return only* nature of the `out` allows us to satisfy all the invariants above without any special casing:

```
c#  
  
public static void ctor(out S @this, ref int f)  
{  
    // The ref-safe-to-escape of `ref f` is *return only* which is also the  
    // safe-to-escape of `this.field` hence this assignment is allowed  
    @this.field = ref f;  
}
```

Method arguments must match

The method arguments must match rule is a common source of confusion for developers. It's a rule which has a number of special cases that are hard to understand unless you are familiar with the reasoning behind the rule. For the sake of better understanding the reasons for the rule we will simplify `ref-safe-to-escape*` and `safe-to-escape` to simply `escape-scope`.

Methods can pretty liberally return state passed to them as parameters. Essentially any reachable state which is unscoped can be returned (including returning by `ref`). This can be returned directly through a `return` statement or indirectly by assigning into a `ref` value.

Direct returns don't pose much problems for ref safety. The compiler simply needs to look at all the returnable inputs to a method and then it effectively restricts the return value to be the minimum `escape-scope` of the input. That return value then goes through normal processing.

Indirect returns pose a significant problem because all `ref` are both an input and output to the method. These outputs already have a known `escape-scope`. The compiler can't infer new ones, it has to consider them at their current level. That means the compiler has to look at every single `ref` which is assignable in the called method, evaluate it's `escape-scope`, and then verify no returnable input to the method has a smaller `escape-scope` than that `ref`. If any such case exists then the method call must be illegal because it could violate `ref` safety.

Method arguments must match is the process by which the compiler asserts this safety check.

A different way to evaluate this which is often easier for developers to consider is to do the following exercise:

1. Look at the method definition identify all places where state can be indirectly returned:
 - a. Mutable `ref` parameters pointing to `ref struct`
 - b. Mutable `ref` parameters with ref assignable `ref` fields
 - c. Assignable `ref` params or `ref` fields pointing to `ref struct` (consider recursively)
2. Look at the call site
 - a. Identify the escape scopes that line up with the locations identified above
 - b. Identify the escape scopes of all inputs to the method that are returnable (don't line up with `scoped` parameters)

If any value in 2.b is smaller than 2.a then the method call must be illegal. Let's look at a few examples to illustrate the rules:

```

ref struct R { }

class Program
{
    static void F0(ref R a, scoped ref R b) => throw null;

    static void F1(ref R x, scoped R y)
    {
        F0(ref x, ref y);
    }
}

```

Looking at the call to `F0` lets go through (1) and (2). The parameters with potential for indirect return are `a` and `b` as both can be directly assigned. The arguments which line up to those parameters are:

- `a` which maps to `x` that has *escape-scope of calling method*
- `b` which maps to `y` that has with *escape-scope of current method*

The set of returnable input to the method are

- `x` with *escape-scope of calling method*
- `ref x` with *escape-scope of calling method*
- `y` with *escape-scope of current method*

The value `ref y` is not returnable since it maps to a `scoped ref` hence it is not considered an input. But given that there is at least one input with a smaller *escape scope* (`y` argument) than one of the outputs (`x` argument) the method call is illegal.

A different variation is the following:

```

c#

ref struct R { }

class Program
{
    static void F0(ref R a, ref int b) => throw null;

    static void F1(ref R x)
    {
        int y = 42;
        F0(ref x, ref y);
    }
}

```

Again the parameters with potential for indirect return are `a` and `b` as both can be directly assigned. But `b` can be excluded because it does not point to a `ref struct` hence cannot be used to store `ref` state. Thus we have:

- `a` which maps to `x` that has *escape-scope of calling method*

The set of returnable input to the method are:

- `x` with *escape-scope of calling method*
- `ref x` with *escape-scope of calling method*
- `ref y` with *escape-scope of current method*

Given that there is at least one input with a smaller *escape scope* (`ref y` argument) than one of the outputs (`x` argument) the method call is illegal.

This is the logic that the method arguments must match rule is trying to encompass. It goes further as it considers both `scoped` as a way to remove inputs from consideration and `readonly` as a way to remove `ref` as an output (can't assign into a `readonly ref` so it can't be a source of output). These special cases do add complexity to the rules but it's done so for the benefit of the developer. The compiler seeks to remove all inputs and outputs it knows can't contribute to the result to give developers maximum flexibility when calling a member. Much like overload resolution it's worth the effort to make our rules more complex when it creates more flexibility for consumers.

Examples of inferred *safe-to-escape* of declaration expressions

Related to [Infer *safe-to-escape* of declaration expressions](#).

C#

```
ref struct RS
{
    public RS(ref int x) { } // assumed to be able to capture 'x'

    static void M0(RS input, out RS output) => output = input;

    static void M1()
    {
        var i = 0;
        var rs1 = new RS(ref i); // safe-to-escape of 'rs1' is CurrentMethod
        M0(rs1, out var rs2); // safe-to-escape of 'rs2' is CurrentMethod
    }

    static void M2(RS rs1)
    {
        M0(rs1, out var rs2); // safe-to-escape of 'rs2' is CallingMethod
    }
}
```

```
}  
  
static void M3(RS rs1)  
{  
    M0(rs1, out scoped var rs2); // 'scoped' modifier forces safe-to-  
    escape of 'rs2' to the current local scope (CurrentMethod or narrower).  
}  
}
```

Note that the local scope which results from the `scoped` modifier is the narrowest which could possibly be used for the variable--to be any narrower would mean the expression refers to variables which are only declared in a narrower scope than the expression.

Extended `nameof` scope

Article • 2022-09-27 • 2 minutes to read

Summary

Allow `nameof(parameter)` inside an attribute on a method or parameter. For example:

- `[MyAttribute(nameof(parameter))] void M(int parameter) { }`
- `[MyAttribute(nameof(TParameter))] void M<TParameter>() { }`
- `void M(int parameter, [MyAttribute(nameof(parameter))] int other) { }`

Motivation

Attributes like `NotNullWhen` or `CallerExpression` need to refer to parameters, but those parameters are currently not in scope.

Detailed design

[Methods](#) ↗

The method's *type_parameters* are in scope throughout the *method_declaration*, and can be used to form types throughout that scope in *return_type*, *method_body*, and *type_parameter_constraints_clauses* but not in *attributes*, **except within a `nameof` expression in *attributes*.**

[Method parameters](#) ↗

A method declaration creates a separate declaration space for parameters, type parameters and local variables. Names are introduced into this declaration space by the type parameter list and the formal parameter list of the method and by local variable declarations in the block of the method. **Names are introduced into this declaration space by the type parameter list and the formal parameter list of the method in `nameof` expressions in attributes placed on the method or its parameters.**

[...]

Within the block of a method, formal parameters can be referenced by their identifiers in *simple_name* expressions (Simple names). **Within a `nameof` expression in attributes placed on the method or its parameters, formal parameters can be referenced by their identifiers in *simple_name* expressions.**

Anonymous function signatures [↗](#)

The scope of the parameters of the anonymous function is the `anonymous_function_body` (§7.7) and `nameof` expressions in attributes placed on the anonymous function or its parameters.

Delegate declarations [↗](#)

The scope of the parameters of the delegate is `nameof` expressions in attributes placed on the declaration, its type parameters or its parameters.

Simple names [↗](#)

A *simple_name* is either of the form `I` or of the form `I<A1, ..., Ak>`, where `I` is a single identifier and `<A1, ..., Ak>` is an optional *type_argument_list*. When no *type_argument_list* is specified, consider `k` to be zero. The *simple_name* is evaluated and classified as follows:

- If `k` is zero and the *simple_name* appears within a block and if the block's (or an enclosing block's) local variable declaration space (Declarations) contains a local variable, parameter or constant with name `I`, then the *simple_name* refers to that local variable, parameter or constant and is classified as a variable or value.
- If `k` is zero and the *simple_name* appears within the body of a generic method declaration and if that declaration includes a type parameter with name `I`, then the *simple_name* refers to that type parameter.
- If `k` is zero and the *simple_name* appears within a `nameof` expression in an attribute on the method declaration or its parameters and if that declaration includes a parameter or type parameter with name `I`, then the *simple_name* refers to that parameter or type parameter.
- Otherwise, for each instance type `T` (The instance type), starting with the instance type of the immediately enclosing type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):
[...]
- Otherwise, for each namespace `N`, starting with the namespace in which the *simple_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
[...]
- Otherwise, the *simple_name* is undefined and a compile-time error occurs.

Scopes [↗](#)

- The scope of a type parameter declared by a `type_parameter_list` on a `method_declaration` is [...] and `nameof` expressions in an attribute on the method declaration or its parameters.
- The scope of a parameter declared in a `method_declaration` (Methods) is the *method_body* of that `method_declaration` and `nameof` expressions in an attribute on the method declaration or its parameters.

File-local types

Article • 2022-10-08 • 5 minutes to read

Summary

Permit a `file` modifier on top-level type declarations. The type only exists in the file where it is declared.

C#

```
// File1.cs
namespace NS;

file class Widget
{
}

// File2.cs
namespace NS;

file class Widget // different symbol than the Widget in File1
{
}

// File3.cs
using NS;

var widget = new Widget(); // error: The type or namespace name 'Widget'
could not be found.
```

Motivation

Our primary motivation is from source generators. Source generators work by adding files to the user's compilation.

1. Those files should be able to contain implementation details which are hidden from the rest of the compilation, yet are usable throughout the file they are declared in.
2. We want to reduce the need for generators to "search" for type names which won't collide with declarations in user code or code from other generators.

Detailed design

- We add the `file` modifier to the following modifier sets:
 - [class](#)
 - [struct](#)
 - [interface](#)
 - [enum](#)
 - [delegate](#)
 - `record`
 - `record struct`.
- The `file` modifier can only be used on a top-level type.

When a type has the `file` modifier, it is said to be a *file-local* type.

Accessibility

No accessibility modifiers can be used in combination with `file` on a type. `file` is treated as an independent concept from accessibility. Since file-local types can't be nested, only the default accessibility `internal` is usable with `file` types.

C#

```
public file class C1 { } // error
internal file class C2 { } // error
file class C3 { } // ok
```

Naming

The implementation guarantees that file-local types in different files with the same name will be distinct to the runtime. The type's accessibility and name in metadata is implementation-defined. The intention is to permit the compiler to adopt any future access-limitation features in the runtime which are suited to the feature. It's expected that in the initial implementation, an `internal` accessibility would be used and an unspeakable generated name will be used which depends on the file the type is declared in.

Lookup

We amend the [member lookup](#) section as follows (new text in **bold**):

- Next, if `k` is zero, all nested types whose declarations include type parameters are removed. If `k` is not zero, all members with a different number of type parameters are removed. When `k` is zero, methods having type parameters are

not removed, since the type inference process ([§11.6.3](#)) might be able to infer the type arguments.

- Next, let F be the compilation unit which contains the expression where member lookup is occurring. All members which are file-local types and are not declared in F are removed from the set.
- Next, if the set of accessible members contains file-local types, all non-file-local types are removed from the set.

Remarks

These rules disallow usage of file-local types outside the file in which they are declared.

These rules also permit *shadowing* of a non-file-local type by a file-local type:

C#

```
// File1.cs
class C
{
    public static void M() { }
}
```

C#

```
// File2.cs
file class C
{
    public static void M() { }
}

class Program
{
    static void Main()
    {
        C.M(); // refers to the 'C' in File2.cs
    }
}
```

Note that we don't update the [scopes](#) section of the spec. This is because, as the spec states:

The **scope** of a name is the region of program text within which it is possible to refer to the entity declared by the name without qualification of the name.

In effect, scope only impacts the lookup of non-qualified names. This isn't quite the right concept for us to leverage because we need to also impact the lookup of qualified names:

C#

```
// File1.cs
namespace NS1
{
    file class C
    {
        public static void M() { }
    }
}

namespace NS2
{
    class Program
    {
        public static void M()
        {
            C.M(); // error: C is not in scope
            NS1.C.M(); // ok: C can be accessed through NS1.
        }
    }
}
```

C#

```
// File2.cs
namespace NS1
{
    class Program
    {
        C.M(); // error
        NS1.C.M(); // error
    }
}
```

Therefore, we don't specify the feature in terms of which scope the type is contained in, but rather as additional "filtering rules" in member lookup.

Attributes

File-local classes are permitted to be attribute types, and can be used as attributes within both file-local types and non-file-local types, just as if the attribute type were a non-file-local type. The metadata name of the file-local attribute type still goes through the same name generation strategy as other file-local types. This means detecting the

presence of a file-local type by a hard-coded string name is likely to be impractical, because it requires depending on the internal name generation strategy of the compiler, which may change over time. However, detecting via `typeof(MyFileLocalAttribute)` works.

```
C#  
  
using System;  
using System.Linq;  
  
file class MyFileLocalAttribute : Attribute { }  
  
[MyFileLocalAttribute]  
public class C  
{  
    public static void Main()  
    {  
        var attribute = typeof(C).CustomAttributes.Where(attr =>  
attr.AttributeType == typeof(MyFileLocalAttribute)).First();  
        Console.WriteLine(attribute); // outputs the generated name of the file-  
local attribute type  
    }  
}
```

Usage in signatures

There is a general need to prevent file-local types from appearing in member parameters, returns, and type parameter constraints where the file-local type might not be in scope at the point of usage of the member.

Note that non-file-local types are permitted to implement file-local interfaces, similar to how types can implement less-accessible interfaces. Depending on the types present in the interface members, it could result in a violation of the rules in the following section.

Only allow signature usage in members of file-local types

Perhaps the simplest way to ensure this is to enforce that file-local types can only appear in signatures or as base types of other file-local types:

```
C#  
  
file class FileBase  
{  
}  
  
public class Derived : FileBase // error  
{
```

```

    private FileBase M2() => new FileBase() // error
}

file class FileDerived : FileBase // ok
{
    private FileBase M2() => new FileBase() // ok
}

```

Note that this does restrict usage in explicit implementations, even though such usages are safe. We do this in order to simplify the rules for the initial iteration of the feature.

```

C#

file interface I
{
    void M(I i);
}

class C : I
{
    void I.M(I i) { } // error
}

```

global using static

It is a compile-time error to use a file-local type in a `global using static` directive, i.e.

```

C#

global using static C; // error

file class C
{
    public static void M() {}
}

```

Implementation/overrides

file-local type declarations can implement interfaces, override virtual methods, etc. just like regular type declarations.

```

C#

file struct Widget : IEquatable<Widget>
{
    public bool Equals(Widget other) => true;
}

```

Generic Attributes

Article • 2022-10-15 • 2 minutes to read

Summary

When generics were introduced in C# 2.0, attribute classes were not allowed to participate. We can make the language more composable by removing (rather, loosening) this restriction. The .NET Core runtime has added support for generic attributes. Now, all that's missing is support for generic attributes in the compiler.

Motivation

Currently attribute authors can take a `System.Type` as a parameter and have users pass a `typeof` expression to provide the attribute with types that it needs. However, outside of analyzers, there's no way for an attribute author to constrain what types are allowed to be passed to an attribute via `typeof`. If attributes could be generic, then attribute authors could use the existing system of type parameter constraints to express the requirements for the types they take as input.

Detailed design

The following section is amended: [§14.2.4.2](#)

The direct base class of a class type must not be any of the following types: `System.Array`, `System.Delegate`, `System.MulticastDelegate`, `System.Enum`, or `System.ValueType`. ~~Furthermore, a generic class declaration cannot use `System.Attribute` as a direct or indirect base class.~~

One important note is that the following section of the spec is *unaffected* when referencing the point of usage of an attribute, i.e. within an attribute list: Type parameters - [§8.5](#).

A type parameter cannot be used anywhere within an attribute.

This means that when a generic attribute is used, its construction needs to be fully "closed", i.e. not containing any type parameters, which means the following is still disallowed:

C#

```
using System;
using System.Collections.Generic;

public class Attr<T1> : Attribute { }

public class Program<T2>
{
    [Attr<T2>] // error
    [Attr<List<T2>>] // error
    void M() { }
}
```

When a generic attribute is used in an attribute list, its type arguments have the same restrictions that `typeof` has on its argument. For example, `[Attr<dynamic>]` is an error. This is because "attribute-dependent" types like `dynamic`, `List<string?>`, `nint`, and so on can't be fully represented in the final IL for an attribute type argument, because there isn't a symbol to "attach" the `DynamicAttribute` or other well-known attribute to.

Drawbacks

Removing the restriction, reasoning out the implications, and adding the appropriate tests is work.

Alternatives

Attribute authors who want users to be able to discover the requirements for the types they provide to attributes need to write analyzers and guide their users to use those analyzers in their builds.

Unresolved questions

- [x] What does `AllowMultiple = false` mean on a generic attribute? If we have `[Attr<string>]` and `[Attr<object>]` both used on a symbol, does that mean "multiple" of the attribute are in use?
 - For now we are inclined to take the more restrictive route here and consider the attribute class's original definition when deciding whether multiple of it have been applied. In other words, `[Attr<string>]` and `[Attr<object>]` applied together is incompatible with `AllowMultiple = false`.

Design meetings

- <https://github.com/dotnet/csharpplang/blob/main/meetings/2017/LDM-2017-02-21.md#generic-attributes> 
- At the time there was a concern that we would have to gate the feature on whether the target runtime supports it. (However, we now only support C# 10 on .NET 6. It would be nice to for the implementation to be aware of what minimum target framework supports the feature, but seems less essential today.)
